## POINTS FOR PRODUCERS.

---

### **Vintage, 1913-14.**

The Government Statist reports that the recent vintage produced 2,759,665galls. of wine, against 3,974,834galls. for the previous season. This represents a decrease of 30·57 per cent., or 1,215,169galls. The average production of wine for each of the last five vintages has been 3,139,191galls. Of the 2,759,665galls. made it is estimated that 1,088,082galls. will be used for distillation ; 19,025 tons of grapes were used, and averaged 145·05galls. of wine per ton, against an average of 156·60galls. for the previous season. Full details of our vineyard and orchard production for the season 1913-14 are expected to be available later.

---

### **Agricultural Co-Operation.**

At the end of 1912, the latest year for which statistics are available, there were 873 registered co-operative societies engaged in agricultural production and distribution in the United Kingdom. Of these 802 were societies engaged wholly in agricultural operations, 450 being engaged in distribution of seeds and manures, implements, and other farmers' requirements, and 352 in the production of butter and other agricultural produce. The 802 societies had a membership of 107,385, or 8 per cent. more than in 1911, and 102 per cent. more than in 1902. The aggregate sales amounted to £5,557,749, showing an increase of 21·5 per cent. since 1911, and of 256 per cent. since 1902. The increases in 10 years seem large, but only because they were small at the beginning of the period. In addition, in 1912 there were 76 industrial co-operative societies which had farming and dairying departments. Co-operation in agricultural production is a plant of slow growth in Great Britain. Including the farming and dairying branches of industrial societies, the number of productive associations increased from 241 in 1902 to 428 in 1912, and the value of the products from £1,580,145 to £3,226,501 ; but 82·6 per cent. of this last sum is credited to Ireland, leaving only 9·9 per cent. for England and Wales, and 7·5 per cent. for Scotland. On the other hand, of the 450 distributive societies 228 belonged to England and Wales, and only 69 to Scotland and 153 to Ireland. In 1902 the number in England and Wales was only 29, while it was one in Scotland and 126 in Ireland. The increase, therefore, says the *Agricultural Gazette*, has been much greater in Great Britain than in Ireland.

**French Silk-Spinning Industry.**

Statistics recently published show a steady decline in the French silk-spinning industry. The total output of spun silk in 1912, the latest year for which particulars are available, was 624,962 kilogs, the lowest total recorded since 1892, and this in spite of the bounties paid amounting to £122,837. There was a slight increase in 1912 in the quantity of silk reeled from French cocoons as compared with 1911 ; but this was more than neutralised by the large decrease in the production of silk from foreign cocoons. The number of spinning mills has also declined. In 1896 there were 280 mills in operation, while in 1912 there were only 177.

**Marketing American Wool.**

*The Board of Trade Journal* for June contains a report from the British Consul-General at Chicago, stating that, according to a local trade paper, the preliminary report of the United States Department of Agriculture inquiry into the methods of marketing American wool shows that from 10 to 20 per cent. of the value of the crop is lost annually through the neglect of a few simple measures. When American and Australian wools are seen side by side in the warehouse the poor handling of the American wool is so noticeable as inevitably to lower its price. It is suggested that this handicap would be largely removed if all growers would agree (a) to put ewe, lamb, and buck fleeces in separate sacks ; (b) to shear black sheep separately and keep their fleeces separate ; (c) to tie the fleeces with paper twine, which does not adhere to the wool ; and (d) to remove the tags and put them in separate sacks marked to show their contents.

**Covering for Tree Wounds.**

The following formula for making a shellac covering for tree wounds, which it is reported has been tried with success in the hot regions of California, where ordinary grafting wax is apt to melt, is given in the *Pacific Rural Press* : " Fill a two-quart glass jar with the flake varnish of shellac, and add enough alcohol to fill the jar half to two-thirds full. Stir until the shellac is dissolved, and then stir in a small cupful of broken or powdered resin. A little lamp-black should be put in the mixture to make it dark, so that no part of the wood will escape being covered, because any exposed part will be easily seen. The dressing should be kept in a closed can or jar to prevent evaporation of the alcohol. Add more alcohol if needed before all the dressing is used. Asphaltum paint (the kind that has been made by dissolving asphalt in benzine, not turpentine) has," says the same paper, " also been found by tree surgeons to be a good covering."

**A Prisoner on Parole.**

"A story is current," says the *Pacific Rural Press*, "that the Governor of Kansas has paroled a State prisoner for 60 days so that he can go to his home and harvest a wheat crop for the support of his family. He was convicted of selling mortgaged property last January, and his family is destitute. The Governor was informed that the wheat which the convict planted last fall promised to yield an abundant crop, and he decided the family needed the convict for the next 60 days more than the State of Kansas did."

**Potato Tops as Forage.**

A note in the *British Board of Agriculture Journal* states that from investigations carried out at the Royal Agricultural High School in Berlin it was concluded that potato tops are equal in value, both as regards chemical composition and digestibility, to good meadow hay; if anything, they are slightly superior to the latter in their proportion of digestible protein. The result of a feeding experiment with dairy cows confirmed this conclusion; the yield of milk and the proportion of fat and dry matter were at least as high as when good meadow hay was fed. If well harvested and made into hay or artificially dried the tops were found to be quite unobjectionable for feeding purposes from a hygienic point of view. When properly prepared they were also found to form good silage, which was willingly eaten. To prevent any unnecessary disturbance of the tubers it is advised that the tops should be cut just before the potatoes are harvested in the normal course. Care should be taken not to include any roots, as the adhering soil might lead to disturbances in the health of the animals.

**Agricultural Laborers' Wages in England.**

*The Mark Lane Express* of May 25th contains reports of various May labor-hiring markets in England. In almost every case all classes of employes offering demanded high wages, and in many instances there were not sufficient to supply the demand. The following examples may be taken as typical of the wages agreed upon for the classes of labor mentioned:—Hawick market—Capable ploughmen, £16 10s. to £19 10s.; others with less experience, up to £15; and lads, £8 to £10 for the half-year with board. Newark—Second wagoners, £20; older hands up to £30; and lads, £10 to £12 per year. Gainsborough—Head wagoners, £20 to £28 per annum; second wagoners, £16 to £20; farm hands, £12 to £10; boys, £10 and upwards. Boston—First wagoners, £21 to £24; second wagoners, £17 to £19; groom-gardeners, £16 to £20; and ploughboys, £10 to £14. Female servants were difficult to obtain at all, the markets and the wages for good generals ruled from £18 to £22 per annum with board.

### Testing Dairy Herds.

Mr. J. T. Young, owner of the dairy herd which won the herd-testing competition conducted by the Tweed River Agricultural Society, is, according to the *Agricultural Gazette of New South Wales*, a strong advocate of testing cows regularly for butter-fat yields. Asked his opinion of the value of such tests, Mr. Young is reported to have said :—"Herd-testing is an essential to ensure a maximum of success in dairying. The dairyman who does not adopt it will certainly be 'left.' During the past 16 years I have used the 'Babcock' on my cows, but not in the systematic manner followed by the herd-testing associations. My custom was to test spasmodically, once or twice a year. The result of my first year's testing in the Byron Bay Herd-Testing Association came as a surprise to me, proving as it did, that irregular testing, as previously carried out by us, was most misleading. I was, indeed, astonished to find that, in spite of previous culling out, I had such a 'tail-end' to my herd. Needless to say, I intend to lop it off as soon as possible. In fact, I have already culled out and speyed nine of my worst producers. These go to the butcher as soon as possible. What a great benefit it is to the dairyman to know which are the best mothers from which to keep heifers to build up his herd by replacing the tail-enders culled out."

### Duration of the Action of Manures.

*The Journal of the Royal Agricultural Society*, (England, 1913) A. D. Hall, M.A., F.R.S.), contains particulars of experiments carried out at Rothamsted in regard to the duration of the action of manures. The facts may be summed up as follows :--As regards farmyard manure, the nitrogenous compounds introduced by the consumption of cakes and other concentrated feeding stuffs, have to be distinguished from the compounds derived from the straw and the undigested residues of such coarse foods as hay. The former will have an immediate effect on the first crop, and to a much smaller extent on the second crop, after which they disappear; the latter compounds act slowly, do not waste, and have a measurable value for many years, though for practical purposes their action after the fourth year may be neglected. Among nitrogenous fertilisers, ammonium compounds and nitrate of soda have no perceptible action after the first year. Peruvian guano, rape cake, and similar fertilisers containing proteins, leave very little residue after the first year, and none after the second. On the other hand, nitrogenous fertilisers of the wool, hair, and bone class are slow-acting and non-wasting, and their effect may be expected to persist for at least four years. Phosphatic fertilisers, even when soluble like superphosphate, do not waste in the soil, and their residues continue to be effective until they have been exhausted in the crops.—*Journal of the Board of Agriculture*.

**Number and Size of Agricultural Holdings in England.**

Rather more than half the agricultural area of England and Wales, according to statistics published in the *Journal of the Board of Agriculture*, is farmed in holdings of over 150 acres, and about one-fourth in holdings of over 300 acres. The occupiers of holdings above 150 acres are few in comparison with the total number of persons who occupy agricultural land, being only 52,000, or 12 per cent. of the total. Nearly one-third of the agricultural area is farmed in holdings from 50 to 150 acres, the number of occupiers of these holdings being 91,000, or 21 per cent. of the total. Holdings from 20 to 50 acres number 78,000, forming 18 per cent. of the total holdings, and representing nearly 10 per cent. of the land under cultivation. The number of holdings from 1 to 20 acres is very large, being nearly one-half of the total, although the area they represent is only 6 per cent. of the whole.

**Import and Export of Fruits, Plants, Etc.**

During the month of July, 1914, 684bush. of fresh fruits, 13,212bush. of bananas, 13,798 bags of potatoes, 557 bags of onions, and 116pkgs. of plants, trees, seeds, and bulbs, &c., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910. Forty-six bushels of bananas (over-ripe) and 4pkgs. of plants (no phylloxera declarations) were destroyed. Under the Federal Commerce Act, 2,382 cases of fresh fruits, 874pkgs. of dried fruit, 70pkgs. of preserved fruit, and 1pkg. of trees were exported to oversea markets during the same period. These were distributed as follows :—For New Zealand, 633 cases of oranges, 1,047 cases of lemons, 600pkgs. of dried fruit, 70pkgs. of preserved fruit, and 1pkg. of trees ; for London, 199 cases of oranges and 174pkgs. of dried fruit ; for Germany, 40 cases of oranges ; for South Africa, 100pkgs. of dried fruit ; for India and the East, 460 cases of apples and 3 cases of oranges. Under the Federal Quarantine Act, 2,593pkgs. of plants, bulbs, seeds, nuts, &c., were examined and admitted from oversea markets.

## INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

### STOCK INQUIRIES.

(Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"S. G.," Parilla, asks—(1) Is it wise to put a mare to horse in same year as she slipped a foal? (2) The best position for a mare requiring help when foaling? (3) Treatment of mare bruised badly during foaling? (4) Treatment of mare if milk is troublesome after passing dead foal? (5) Treatment for mare having swelling along belly when weaning foal?

Reply—(1) It depends on circumstances; if health appears good, yes. (2) Depends on circumstances; generally speaking, with hindquarters uphill, or raised, whether standing or lying. (3) Keep comfortable and warm, give soft food with an ounce or two of Epsom salts in drinking water, wipe bruised parts with warm milk containing a teaspoonful of tinct. arnica to the pint. (4) Ease udder only if much pain. Rub with warm soapsuds. Give hypsulphite of soda (photographer's hypo.), 1oz. twice a day in water or mash. (5) Similar to above, with 10 drops tinct. belladonna twice daily, and let foal reduce udder if painful.

"W. H. S." asks advice concerning horse which has had a hard dry cough for six months; worse when driven. Its coat and condition is all right; cough is variable.

Reply—The symptoms of broken wind (asthma), a condition which cannot be cured, as the lung tissue is broken down; relief may be obtained by feeding a little at a time and often—no dusty hay, only bright chaff and corn, with a tablespoonful of olive or linseed oil in it once a day. Ten drops of tinct. aconite on the tongue morning and evening for a month may improve matters somewhat; or aconite may be given in the morning and 10 drops of tinct. digitalis in the evening; but one must not expect a cure, only relief.

"F.," Elbow Hill, had a horse which, when drinking, would stand over trough with head outstretched and lip turned up. He asks cause.

Reply—The symptoms occur in the case of toothache and catarrh of the stomach; an inspection of the mouth would decide if the former. Try a heaped teaspoonful of baking soda in the food once daily for a month.

"A. B." asks treatment for horse suffering from ringbone.

Reply—There is no treatment for ringbone.

"A. J. H.," Coonawarra, asks what to do for mare in foal, which stamps switches her tail, and passes worms about 2in. long. Also treatment for colt which stops to urinate every half-hour, and has mange on shoulders.

Reply—The worms, *Oxyuris curvula*, or whipworm, live in the hinder bowel and irritate. If the mare were not in foal the best thing would be to warm a quart of milk, add two or three tablespoons of turpentine, and inject; the worms would then be brought away. As she is in foal, make a strong brine of salt and water and inject a quart or two. Beyond the irritation the worms are not injurious. Salt fed to the mare will also turn them out. Frequent urination is probably due to an irritant in the urinary tract; wash out sheath and yard with warm soap and water, and give ten drops of tincture of camphor in a little honey morning and evening for a week—just put it on the tongue. For the mange, stand the colt in the sun for an hour or so, then wash with soft soap and water, leaving the soap to dry on, next day wash it off and dress with benzine one part and cheap oil five parts; repeat the dressing daily for three days, then fortnightly for three times.

"J. T. M.," Spalding, has some horses which have had strangles; a pony now has a huge swelling at angle of jaw; there is some discharge, and pony has great difficulty in breathing.

Reply—The strangles abscess has formed in the parotid gland. Steam the head well with a teaspoonful of turpentine in the water; feed from the ground, and put a tablespoonful of Fowler's solution of arsenic in the food once a day for a week or two. Foment the swelling and rub in hot lard; encourage it to break naturally, but do not try to lance, as there are big blood vessels in the neighborhood; after it has discharged paint inside and out with tincture iodine.

"E. L. S." asks for treatment for colt rising two years suffering from blood worms.

Reply—The dose of Fowler's solution of arsenic for such a colt is—One tablespoonful once a day for a fortnight in feed, stop for a fortnight, repeat for fortnight. A horse takes two tablespoonfuls.

"J. D.," Belalie, seeks information concerning (1) ram, 4-tooth, which died 11 days after castration, before death became very stiff, hardly able to bend

legs ; (2) wether, 4-tooth, which stretches, falls, and kicks about as if in pain ; (3) ewe which became bad three days before lambing a dead lamb, similar last year, when recovered, but lost all her wool.

Reply—(1) Either lockjaw or blood poisoning, either of which is common in the ram ; the old-fashioned verdigris ointment is recommended after the operation. (2) Probably wool balls in the paunch, or worms ; give two table-spoonfuls of castor oil, and try Cooper's worm tablets. (3) Some deformity of genital passages ; as she is full-mouthed it would be better not to breed from her again.

“ W. S. C.,” Criscal Brook, treated mare which was ill all day, groggy on legs, blind and deaf, was not colicky, with sedatives and stimulants, and she recovered. He asks was it meningitis ?

Reply—Probably not, though the symptoms would lead one to suspect it ; the attack is commonly called stomach staggers, and means that there is congestion of the great nerve centres of the brain and spinal cord. The linseed oil and ammonia probably helped on the recovery. The treatment should begin with a purgative, and even now she would probably be better for a 6-dram aloes ball, or 4ozs. of Epsom salts once a day for three or four days to clean out the system. To prevent, feed bran freely.

“ E. W. C.” inquires treatment for horse which was off feed, passed urine dark and scanty, dung ditto, with foul smell and appearance of rotten skin on it.

Reply—The symptoms point to congestion of the liver and bowel irritation. Not knowing what drugs have been used, it is a little difficult to advise ; but probably improvement would follow the use of a tablespoonful of sulphur once a day in the feed.

“ H. J. F. H.” asks treatment for filly which has become blind, presumably through eating paddymelon.

Reply—Bleed two quarts, give aloes ball 5 drams ; when scouring is over give a tablespoonful of sulphur in food once a day for a fortnight.

“ T. A. S.,” Laura, inquires treatment for colt suffering from a cold, with running at nose, swelling of legs, especially hind, hair falling off, and weakness.

Reply—The usual symptoms of influenza, so called, which, as surmised, is a form of blood poisoning. In such a case it is well to give 1oz. of hyposulphite of soda twice a day in bran for a few days ; but when the disease has existed for some time then probably greater good will be obtained by giving a table-spoonful of Fowler's solution of arsenic once daily in the food for a fortnight.

“ C. E. B.,” Clare, asks how horse with canker of the foot of long standing should be treated.

Reply—As the case is of long standing it is a little doubtful whether treatment will be successful ; but probably if the diseased tissue is cut away, the

foot dressed daily with a mixture of two tablespoonfuls of formalin to a pint of methylated spirit, and occasionally with a little dry calomel, and the animal worked on the land, it may improve. It will be of advantage to give two tablespoonfuls of Fowler's solution of arsenic once daily in the food for a month.

A member of the Leighton Agricultural Bureau reports that, as a result of *post mortem* on horse, bots were found on diaphragm. He asks if this is at all usual, as members were under the impression that bots were not found other than in the stomach.

Reply—The usual place to find bots is at the exit from the stomach, but other varieties inhabit the gullet and hinder gut, and in this case probably those found had come from the gullet, as it would be cut to remove the stomach.

"R. J. R." seeks treatment for mare which has gone very lame near side foreleg, possibly through having sprained tendon.

Reply—There seems a suggestion of laminitis; but if it is really a sprained tendon, such as you suppose, it would be best to put on a coat of tar, wool, tar, till a permanent bandage about  $\frac{1}{2}$  in. thick is sticking all round the leg, and then leave the bandage to come off.

"B. B.," Koolunga, had aged mare which went off her feed and was scoured; the feed was changed and she was treated with castor and linseed oil and nux vomica. She got weaker, but was put on green wheat during day, treatment being continued, and after a while showed improvement. Appeared to be doing fairly, but one night was found with bowels protruding and in great pain, and had to be shot. *Post mortem* revealed rupture of internal organs and sand in bowel. He asks, was sand the cause of her illness, and was it possible for the sand to have been in her bowel for several months?

Reply—She might have had the sand some weeks, but probably it was more recent, and was not directly concerned with her death. The earlier symptoms were connected with abscesses in the stomach, and the acute final symptoms arose from distension and bursting of that organ from gases evolved from the wheat. The treatment was quite correct all through, and her death may be looked upon as unavoidable.

"H. J. S.," Harrowgate, asks treatment for a horse which chokes and coughs up slime when eating, and makes a noise when drinking, which act is difficult.

Reply—There is obstruction, probably an abscess, in the throat, and relief would be gained by well steaming the head with a few drops of Eucalyptus oil in the water. Rub the throat well with embrocation. Put a tablespoonful of a mixture made of equal parts glycerine, honey, and Stockholm tar upon the teeth once or twice a day.

"N. P. T." forwarded part of lung of cow which died suddenly.

Reply—The piece of lung received contained hydatid cysts (*Echinococcus multilocularis*), no doubt the rotten and cheesy parts were degenerated cysts. The adult form of the worm *Taenia echinococcus* occurs in the dog, so if other cows are affected it would be well to dose the dogs and destroy their dung. The same cysts occur in man as hydatids.

"Frances" seeks advice concerning cow which has become blind in two teats, possibly result of injury.

Reply—Probably the secreting cells of the udder are destroyed and nothing can be done. If not, try opening the teats with a teat syphon, and if milk is obtained foment the udder well twice a day with hot soapsuds.

#### POULTRY.

A member of the Cherry Gardens Agricultural Bureau has two Muscovy ducks, the live weights of which, when three months, were respectively 8lbs. 2ozs. and 7lbs. 10ozs. He asks if they constitute a record.

Reply—The Poultry Expert (Mr. D. F. Laurie) replies:—I cannot say if the weights given are records. At any rate, they are splendid weights, and show what can be done with the Muscovy breed, pure or cross.

#### MANURING AND SOIL FERTILITY.

"H. L." asks titles of books on manuring and soil fertility which can be understood by persons not having had a technical education.

Reply—Professor Perkins recommends "Feeding of Crops and Stock" and "Manures," both by A. D. Hall, M.A., F.R.S.

#### SHEEP ON RAPE.

"W. H.," Woodside, asks whether it is safe to turn ewes and lambs on to rape while damp from rain or dew, providing they are not kept for long on it.

Reply—Professor Perkins replies—I do not anticipate that your flock is likely to suffer from feeding off the rape, on the understanding, of course, that they are not brought into the field in a famishing condition. Indeed, in my experience, sheep do not at first take very readily to rape, and are therefore not in much danger of eating too much of it when first introduced into the field.

#### HORTICULTURE.

The Watervale Agricultural Bureau asks,—(1) Is leaving small and unmarketable apples on a tree for the purpose of allowing them to grow, detrimental to the tree and the following year's crop? (2) Is spraying with bluestone alone to be recommended for winter spraying for peaches and apricots?

Reply—The Horticultural Instructor (Mr. Geo. Quinn) replies—(1) If the tree is suffering severely from lack of moisture, as has been the case in most localities this year, the fruit which is deemed useless should be pulled off without delay, as its presence towards the end of the season's growth will certainly injuriously affect the prospects of the flower buds reaching maturity. (2) Bluestone at the rate of 1lb. to 15galls. of water makes an excellent winter spray for peach and apricot trees, but its effectiveness is increased against the shothole fungi if applied just as the leaves fall in the very early portion of the winter.

---

## EXPERIMENTS WITH "FRENLER" AGAINST CODLIN MOTH.

---

By Inspector R. FOWLER, Mount Gambier.

Inspector R. Fowler, Mount Gambier, has submitted to the Chief Inspector of Fruit (Mr. Geo. Quinn) the following report :—

"During the season I carried out some minor experiments with 'Frenler' for the destruction of codlin moth. I obtained  $\frac{1}{2}$  gall. of the mixture and some 24 bottles and used them in four different gardens with the following results :—F. Webster's garden, Mount Gambier, to end of December, two codlin moths ; A. Shelton's garden, Mount Gambier, to end of December, 56 codlin moths ; A. Kieselbach's garden, Mount Gambier, to end of December, 24 codlin moths ; Fowler Bros.' garden, Coonawarra, to end of December, 20 codlin moths ; total 102. In addition, I also trapped a number of small insects, mostly vinegar flies, and a number of bees.

"I found that the bottles required refilling about every fortnight or so ; and to look after a number of them would require a good deal of time and labor. The best catch was in Shelton's garden, and there I got the 56 moths the first week with only two bottles, but had no luck afterwards. Speaking of this catch to Mr. Arthur M. Lea, Entomologist at the South Australian Museum, he remarked that possibly the greater proportion of them were males, they being much more likely to be caught than the females.

"Mr. H. B. Richardson also tried this preparation, but with bad results. In his case he did not spray the trees ; but in my experiments all the trees were sprayed as well. He found that the trees with the 'Frenler' bottles were much worse with codlin moth than usual.

"From results obtained I am quite satisfied that 'Frenler' is not keeping down codlin moth."

## ROSEWORTHY AGRICULTURAL COLLEGE.

FIFTH REPORT ON THE PERMANENT EXPERIMENT FIELD,  
1905-1914.

By ARTHUR J. PERKINS, Principal Roseworthy Agricultural College,  
and W. J. SPAFFORD, Assistant Experimentalist.

*(Continued from page 1268.)*

## ROTATION PLOTS.

## SUMMER CROP—WHEAT ROTATION.

(Plots 12 and 13.)

The practice of causing a wheat crop to be preceded immediately by a horse-hoed summer crop is, in principle, attractive enough, and in earlier days we find this form of rotation to have been very widely recommended for Lower North conditions. The theoretical aspect of this question may, perhaps, be summarised as follows :—To cause a wheat crop to be preceded by 12 months of bare fallow, during the course of which the land lies quite idle, is economically wasteful ; if, on the other hand, we substitute for bare fallow a horse-hoed summer crop, we shall be turning to better advantage the economic possibilities of the land. A proposition of this kind would no doubt be correct if it could be proved that the combined net returns from the two crops—summer crop and wheat—appreciably exceeded those from the wheat crop alone, when preceded by simple bare fallow. And the exclusion of bare fallow, and the adoption of a second crop, would then be a sign of progress, which has usually characterised the improvement of agricultural practice by gradually swelling populations. Moreover, if the influence of climatic conditions can be shown to be such that the summer crop must have the effect of reducing somewhat the yield of the wheat crop that follows it, relatively to that of wheat grown after bare fallow, then the intrinsic value of the summer crop must be sufficiently great amply to compensate any loss that might arise in this connection.

The summer crop that has been adopted by us in the course of these experiments has been, with the exception of two seasons, Early Amber Cane

sorghum ; in 1910 and 1911-Pennicillaria was tested instead. We cannot claim that these summer crops have been particularly successful. In the first instance, however, we propose drawing attention to their influence on the wheat crop that followed. Below in Table XIII. we have summarised the yields of wheat after sorghum with those of wheat after bare fallow between 1906 and 1913.

TABLE XIII.—*Showing Yields of Wheat after Sorghum comparatively with Yields of Wheat after Bare Fallow, 1906-1913.*

| Year.   | Total Produce per Acre. |            |                          |            | Grain per Acre.      |      |                          |      | Bushel Weight        |                          |
|---------|-------------------------|------------|--------------------------|------------|----------------------|------|--------------------------|------|----------------------|--------------------------|
|         | Wheat after Sorghum.    |            | Wheat after Bare Fallow. |            | Wheat after Sorghum. |      | Wheat after Bare Fallow. |      | Wheat after Sorghum. | Wheat after Bare Fallow. |
|         | Tons                    | cwts. lbs. | Tons                     | cwts. lbs. | Bush.                | lbs. | Bush.                    | lbs. | lbs.                 | lbs.                     |
| 1906    | 2                       | 0 39       | 2                        | 8 100      | 18                   | 3    | 23                       | 43   | 57                   | 58½                      |
| 1907    | 0                       | 17 22      | 1                        | 8 88       | 13                   | 7    | 20                       | 31   | 61½                  | 62½                      |
| 1908    | 2                       | 9 96       | 2                        | 11 26      | 28                   | 16   | 32                       | 46   | 63½                  | 64½                      |
| 1909    | 2                       | 1 49       | 2                        | 7 61       | 20                   | 44   | 29                       | 54   | 62½                  | 62½                      |
| 1910    | 2                       | 0 44       | 2                        | 5 98       | 18                   | 25   | 19                       | 49   | 63½                  | 64½                      |
| 1911    | 1                       | 3 8        | 1                        | 8 9        | 12                   | 38   | 14                       | 7    | 64½                  | 63½                      |
| 1912    | 1                       | 10 33      | 1                        | 6 32       | 20                   | 18   | 18                       | 11   | 64                   | 65½                      |
| 1913    | 0                       | 8 39       | 0                        | 10 19      | 3                    | 19   | 5                        | 4    | 61½                  | 60                       |
| Means   |                         |            |                          |            |                      |      |                          |      |                      |                          |
| 1906-13 | 1                       | 11 55      | 1                        | 15 96      | 16                   | 51   | 20                       | 31   | 62½                  | 62½                      |

Table XIII. shows very clearly the depressing influence of a crop of sorghum on the wheat crop that follows under Roseworthy conditions of climate. If we take the average results of eight years we see that the average grain yield of wheat after bare fallow was 3bush. 40lbs. in excess of that of wheat after sorghum, which, at 3s. 6d. a bushel, represents a difference in annual returns of 12s. 10d. per acre.

Similarly, in the matter of total produce the difference in favor of wheat grown after bare fallow is represented by 4cwts. 41lbs. per acre, or in terms of wheaten hay 5cwts. 37lbs. per acre, representing at 35s. a ton a value of 9s. 4d. per acre. Another feature worth noting in this connection is that almost invariably the bushel weight of wheat grown after bare fallow proved superior to that of wheat grown after sorghum ; a fact which, independently of yields, gives added commercial value to wheat grown after bare fallow.

We see, therefore, that in this district, according to our results, the immediate effects of taking a crop of sorghum off fallow land is to depreciate the succeeding wheat crop to the extent of 10s. to 13s. per acre. And if we are to reap any direct benefit from the practice the net returns from the sorghum crop must, if they do not exceed it, at least equal this unavoidable loss. We have already pointed out that we have not been particularly successful with sorghum in this field, and the chief cause of our failures in

this direction lies, we believe, in the character of the soil, which, in our view, is too heavy for sorghum grown without the aid of irrigation. And whilst we are bound to indicate below the results we have had to put on record, we feel that they should not be taken to prejudice the real value of sorghum, in which, under more favorable conditions, we have great faith.

In seasons 1906-7 and 1907-8 the sorghum crops were cut with a mower and fed to cattle; in each case the yields were exceedingly unsatisfactory, being respectively 1,006lbs. and 586lbs. to the acre. Yields of this kind do not pay for the cultivation of the crop.

In seasons 1908-9 and 1909-10 the sorghum crops were fed off in the field by cattle. In the first season the sorghum crop maintained cattle for four days at the rate of 10.61 head to the acre, and aggregating in weight 6,845lbs. If we assume that an average sheep weighed 100lbs., this would represent about 68 sheep to the acre for four days, or three-quarters of a sheep per acre per annum.

In the second season the sorghum crop carried cattle at the rate of 5.58 head per acre for 10 days; their aggregate weight was 4,414lbs., representing the equivalent, therefore, of about 44 sheep, or 1.12 sheep per acre per annum.

In the 1910-11 season the sorghum crop was fed down with sheep at the rate of 26.43 sheep per acre for 13 days, or the equivalent of 0.94 sheep per acre per annum.

In 1911-12 the sorghum crop was a complete failure, from lack of summer rains sufficiently heavy and well-timed to bring about good germination.

In 1912-13 the sorghum crop was again fed down with sheep at the rate of 14.74 sheep per acre for 18 days, or the equivalent of 0.73 sheep per acre per annum.

In 1913-14 the sorghum plot was split up into two sub-plots, one of which was dressed with farmyard manure at the rate of 14 tons to the acre, whilst the other half was treated in the ordinary way. The sub-plot dressed with farmyard manure carried sheep for five days at the rate of 61.89 per acre, or the equivalent of 0.85 sheep per acre per annum; whilst the sub-plot treated in the ordinary way carried sheep for three days at the rate of 61.48 per acre, or the equivalent of 0.51 sheep per acre per annum.

It must be said without hesitation that none of the results indicated above can be taken to justify the growing in this district of sorghum as a summer fallow crop. At the same time, these results notwithstanding, we must confess to having retained our faith in the value of sorghum as a summer forage crop adapted to the normal conditions of the district. By way of illustration we will state that under more favorable conditions a well-grown crop of sorghum has, on the College Farm, carried sheep at the rate of 45 to the acre for a period of 47 days, or the equivalent of more than six sheep

to the acre per annum. Results of this kind, when obtainable, would represent a gross return of about £4 10s. per acre, which more than compensate the cost of production coupled with the depressing influence of the sorghum crop on the yield of the wheat crop following it. In our view, therefore, sorghum can be utilised advantageously in this district as a summer fallow crop only in the lighter types of soil, and well grown, supplies an abundance of valuable summer forage; at the same time, that it exercises a depressing influence on the wheat crop that follows cannot be denied.

#### NORFOLK FOUR-COURSE ROTATIONS.

We have already intimated that the Norfolk four-course rotation has in past years been represented in the Permanent Experiment Field by two variants, viz.—

|                   | Rotation A. | Rotation B. |
|-------------------|-------------|-------------|
| First year .....  | Turnips ..  | Kale        |
| Second year ..... | Barley ..   | Oats        |
| Third year .....  | Peas ..     | Vetches     |
| Fourth year ..... | Wheat ..    | Wheat       |

It must be admitted that latterly the seasons have proved altogether unpropitious to cropping rotations of this type; and in the present season we have definitely decided to do away altogether with rotation B and replace it by the following new rotation:—

|                   |             |                   |         |
|-------------------|-------------|-------------------|---------|
| First year .....  | Bare fallow | Fourth year ..... | Lucerne |
| Second year ..... | Wheat       | Fifth year .....  | Lucerne |
| Third year .....  | Lucerne     |                   |         |

We summarise below in Table XIV. the data of the wheat crops raised in these two rotations comparatively with those of wheat grown regularly after bare fallow since 1908—the first season in which the four-course rotation was completed.

TABLE XIV.—*Showing Returns from Wheat grown in Rotations A and B comparatively with Wheat grown regularly after Bare Fallow, 1908-13.*

| Seasons.   | Grain Yields. |            |             |            |                    | Total Produce Yields. |                |                |                |                    |  |

| 1910 ....  | 23 22         | 22 6       | 19 49       |            |                    | 2 9 38                | 2 9 24         | 2 5 98         |                |                    |  |
| 1911 ....  | 16 36         | 9 55       | 14 7        |            |                    | 1 15 29               | 1 3 10         | 1 8 9          |                |                    |  |
| 1912 ....  | Fed off       | Fed off    | 18 11       |            |                    | Fed off               | Fed off        | 1 6 32         |                |                    |  |
| 1913 ....  | 0 54          | 1 33       | 5 4         |            |                    | Stripped              | Stripped       | 0 10 19        |                |                    |  |
| Means .... | 16 0          | 15 44      | 19 59       |            |                    | ?                     | ?              | 1 14 97        |                |                    |  |

It will be noted from the above results that in favorable seasons like 1908, 1909, and 1910, wheat grown in regular rotation with other crops on land that had not been fallowed since 1904 yielded results quite equal to those of wheat grown regularly after a year of bare fallow. In 1911—a moderate season—the results from rotation wheat on land that had not been fallowed for eight years were still good. In 1912, however, seeding weather was so unsatisfactory, and germination was so poor, that the rotation wheat was completely smothered out by weeds, and we were compelled to feed it off with sheep. Finally, in 1913—another exceptionally bad year—rotation wheat suffered far more than wheat grown after bare fallow. It may be noted, too, that in the mean yield of the six years under consideration there is a difference of about 4 bush. in favor of wheat grown after bare fallow, including, of course, the season in which no rotation wheat at all was harvested. We are very far from thinking that the results of these six years must settle definitely the fate of rotation wheat in this district; the proportion of abnormally bad seasons—33 per cent.—is too great to permit of definite conclusions on the subject, and we must leave it to future years to show what may be expected from wheat grown in rotation under more normal conditions of climate.

We may now proceed to consider the results from the other crops grown in rotation with wheat.

### TURNIPS.

It cannot be said that under our conditions of climate, turnips have, as a field crop, anything like the economic value that attaches to them in colder latitudes. In England and New Zealand they are unquestionably invaluable to the sheepowner; and this, because they supply him with an abundance of succulent feed in the winter months of the year when nothing else is available. Such a contingency, however, is possible only in those countries in which turnips admit of being treated as a biennial crop sown in spring or early summer, making its growth during the summer months, lying dormant throughout the winter, when it becomes available for feeding purposes; and if undisturbed, not running to seed until the spring that follows seeding operations. Local conditions, however, do not admit of any such treatment; we cannot, in this district at all events, hope to raise successfully spring-sown turnips; and we are unavoidably thrown back upon autumn sowing. This will mean that the crop will make its main growth in winter, and become available for feeding in spring, a time of the year when feed in various forms, far less costly to raise, is usually available to us. Moreover, this winter-raised turnip crop must always be grazed off very rapidly, since the first warm days inevitably send it to seed. In the circumstances we are

very doubtful of the value of turnips as a rotation crop for the district. At the outside, on a small scale, where the land is light and farmyard manure available, turnips might, perhaps, occasionally be raised with advantage for the purpose of "spelling" in spring other pasture land. That the feeding value of autumn-sown turnips is certainly good, the figures in Table XV. will serve to show; and in this connection it should be recalled that the heavy soil of the Permanent Experiment Field is by no means ideal from the point of view of a turnip crop.

TABLE XV.—*Showing Feeding Value of a Turnip Crop in the Permanent Experiment Field.*

| Season.    | Number of Days<br>Grazed. | Sheep per Acre<br>for Number of<br>Days Grazed. | Equivalent Grazing<br>Value in Sheep<br>per Acre per Annum. |
|------------|---------------------------|-------------------------------------------------|-------------------------------------------------------------|
|            | Sheep.                    | Days.                                           | Sheep.                                                      |
| 1907 ..... | 54.11                     | 21                                              | 3.25                                                        |
| 1908 ..... | 47.12                     | 21                                              | 2.71                                                        |
| 1909 ..... | 38.01                     | 34                                              | 3.54                                                        |
| 1910 ..... | 25.53                     | 45                                              | 3.15                                                        |
| 1911 ..... | 39.65                     | 18                                              | 1.96                                                        |
| 1912 ..... | 18.82                     | 39                                              | 2.01                                                        |
| 1913 ..... | 16.01                     | 17                                              | 0.75                                                        |
| Mean ..... | —                         | —                                               | 2.48                                                        |

We gather, therefore, that over a period of seven years, the two last of which were altogether unfavorable to turnips, the grazing value of the crop was equivalent to about two and a half sheep per acre per annum; under more favorable conditions we believe that three sheep per acre per annum would more correctly represent the grazing value of this autumn-sown crop. It should be added that in the rotation plots this crop always has been dressed with farmyard manure.

Both in 1909 and 1910 a careful record of the weights of sheep grazing on the turnip plots was taken, and as the results noted present a certain amount of interest they will be indicated here. In 1909, when the sheep-carrying capacity of the turnip crop was shown to be equivalent to 3.54 sheep per acre per annum, the total increase in weight noted for 34 days' grazing was 754.91lbs. per acre distributed among 38.01 sheep. This represents a daily individual increase in weight of the sheep of 0.58lbs. In 1910, when the sheep-carrying capacity of the turnip crop was shown to be equivalent to 3.15 sheep per acre per annum, the total increase in weight noted for 45 days' grazing was 426.29lbs. per acre distributed among 25.53 sheep, and representing an average individual increase in weight of 0.37lbs. per diem.

## BARLEY.

Barley, which is preceded by turnips and followed by pease, represents the second crop in rotation A. We append below in Table XVI. results secured from it since 1905.

TABLE XVI.—*Showing results secured from Barley in Four-Course Rotation A, 1905-1913.*

| Season.             | Grain<br>per Acre.<br>Bush. lbs. | Total Produce<br>per Acre.<br>Tons cwt. lbs. |
|---------------------|----------------------------------|----------------------------------------------|
| 1905 .....          | 57 32 ..                         | 3 8 3                                        |
| 1906 .....          | 25 36 ..                         | 2 1 14                                       |
| 1907 .....          | 10 29 ..                         | —                                            |
| 1908 .....          | 18 32 ..                         | 1 12 16                                      |
| 1909 .....          | 30 23 ..                         | 1 19 32                                      |
| 1910 .....          | 42 49 ..                         | 2 6 85                                       |
| 1911 .....          | 32 38 ..                         | 1 14 108                                     |
| 1912 .....          | 33 43 ..                         | 1 17 41                                      |
| 1913 .....          | 3 29 ..                          | —                                            |
| Means 1905-13 ..... | 28 23 ..                         | —                                            |
| Means 1908-13 ..... | 27 2 ..                          | —                                            |

The total produce cannot be given for 1907 and 1913, because in these two years the crop was too short for binding and was accordingly stripped. It will be noted that in this rotation the barley yield is not far from double that of the wheat yield for the 1908-13 period.

## PEASE:

The pea crop follows the barley crop and immediately precedes the wheat crop in rotation, and is, therefore, the third crop. In the earlier years of these experiments we endeavored to harvest the pea crop; the results were, however, too unsatisfactory to be continued, and from 1908 the pea crop was treated as a forage crop; and it is from the latter point of view alone that we propose dealing with it here.

In this connection it should be noted that a forage pea crop cannot in a four-course rotation of the type we have under consideration be handled in the way that is open to those who merely sow pease on wheat stubbles. In the latter case the pease are usually allowed to mature, and dry haulms and pods are subsequently fed down in the summer months of the year. In our case, however, the pea crop precedes instead of following the wheat crop; and it cannot be allowed to interfere with the prospects of the most important crop in the rotation. Hence, it follows that the pea crop must be fed off as early as circumstances permit of, in order to allow of ample time to get the land ready for the wheat crop. There is another important reason that renders early grazing of the pease imperative in this case; if the pease are allowed to mature, weeds, which always grow very rankly in a

pea crop, will run to seed, much to the detriment of the wheat crop that follows. In this rotation, therefore, one is compelled to graze or cut the forage pea crop in the spring.

In 1909 and 1912 the pea crop was cut with the mower, whilst in the other years it was grazed with sheep. We shall proceed to examine results in either case.

1909.—The pea crop was cut between August 17th and September 26th (41 full days) and fed regularly to steers. The total yield per acre was represented by 9 tons 11cwts. 46lbs. of greenstuff. During that period six steers received 41,556lbs., or at the rate of 169lbs. each per diem. The aggregate original weight of these steers was 4,895lbs., and their aggregate finishing weight 5,499lbs.; this represents a total increase in weight of 604lbs., or 2·46lbs. per steer per diem. This pea crop, therefore, supported steers at the rate of 3·1 per acre for 41 days; and during that period they put on weight at the rate of close on 2½lbs. per diem each; the equivalent steer-carrying capacity per annum works out to 0·35 steers per acre per annum. In addition to this the pea stubbles were subsequently grazed with sheep for 12 days at the rate of 9·22 sheep per acre, or the equivalent of 0·30 sheep per acre per annum.

1912.—In 1912 the pea crop was far less well grown; it was cut with the mower and turned into ensilage; hot weather had dried it off considerably, and it only went 2 tons 3cwts. 59lbs. to the acre of greenstuff. Incidentally, it may be stated, as a result of our experience, that we know of no crop that makes more satisfactory ensilage than a well-grown pea crop. The stubbles were subsequently grazed by sheep for 28 days at the rate of 11·27 sheep per acre, or the equivalent of 0·86 sheep per acre per annum.

#### PEA CROPS GRAZED BY SHEEP.

In 1908, 1910, 1911, and 1913 the pea crops of these plots were simply grazed by sheep; results secured are shown below in Table XVII.

TABLE XVII.—*Showing Grazing Capacity of Rotation Pea Crops in 1908, 1910, 1911, and 1913.*

| Season.    | Number of Days<br>Grazed. | Sheep per Acre<br>for Number of<br>Days Grazed. | Equivalent Grazing<br>Value in Sheep<br>per Acre per Annum. |
|------------|---------------------------|-------------------------------------------------|-------------------------------------------------------------|
|            | Days.                     | Sheep.                                          | Sheep.                                                      |
| 1908 ..... | 43                        | 14·56                                           | 1·71                                                        |
| 1910 ..... | 36                        | 25·75                                           | 2·54                                                        |
| 1911 ..... | 12                        | 57·11                                           | 1·88                                                        |
| 1913 ..... | 8                         | 32·81                                           | 0·72                                                        |

#### THOUSAND-HEADED KALE.

Four-course rotation B has opened with a kale crop since 1908; it cannot be said, however, that during this period of six years we have succeeded in

raising a good typical kale crop, like the 1905 farm crop. It should be recollected that with us kale is autumn-grown, and in these circumstances the great difficulty with this crop is to get it to germinate sufficiently early in the season. May germination, which is usual in this district, is equivalent to an attempt to growing cabbages sown at that time of the year; that is to say, courting partial failure under the most favorable of conditions. The late germinated kale plants never make sufficient growth to develop into a heavy forage crop. In the circumstances we are forced to the conclusion that a good crop of kale cannot be anticipated in this district, except in autumns exceptionally early and exceptionally favorable. We append below in Table XVIII. what we found to be the grazing value of our kale crops in the plots of the Permanent Experiment Field. We must add that these figures are very far from doing justice to kale as a forage crop when grown under more favorable conditions.

TABLE XVIII.—*Showing the Grazing Value of Thousand-Headed Kale in Rotation, 1908-1913.*

| Season.            | Number of Days<br>Grazed. | Sheep per Acre<br>for Number of<br>Days Grazed. | Equivalent Grazing<br>Value in Sheep<br>per Acre per Annum. |
|--------------------|---------------------------|-------------------------------------------------|-------------------------------------------------------------|
|                    | Days.                     | Sheep.                                          | Sheep.                                                      |
| 1908 .....         | 81                        | 7.63                                            | 1.69                                                        |
| 1909 .....         | 58                        | 15.08                                           | 2.40                                                        |
| 1910 .....         | 45                        | 25.38                                           | 3.13                                                        |

#### OATS.

In the second year the land comes under oats in rotation B; this crop is preceded by kale and followed by vetches. Grown under these conditions oats have shown themselves altogether inferior to barley as a rotation crop for the district. The results of the eight seasons, 1906-1913, are summarised below in Table XIX.

TABLE XIX.—*Showing Returns from Oats grown in Rotation, 1906-1913.*

| Season.             | Total<br>Produce<br>per Acre. | Grain<br>per Acre. |
|---------------------|-------------------------------|--------------------|
|                     | Tons cwt. lbs.                | Bush. lbs.         |
| 1906 .....          | 1 18 78                       | 36 34              |

## VETCHES.

Vetches have represented, since 1908, the leguminous crop preceding wheat in rotation B, and they have themselves always been preceded by an oat crop. In 1909 this crop was, like pease in rotation A, partly fed to steers and partly used for ensilage purposes; whilst in 1912 it was wholly turned into ensilage. In 1908, 1910, 1911, and 1913 the vetches were grazed off by sheep.

1909.—The total yield per acre of the vetches cut in the green stage was 10 tons 11cwt. 75lbs., *i.e.*, about 1 ton to the acre better than the pea crop cut in the same season and under similar conditions. Between September 27th and October 14th (inclusive), a period of 18 days, 14,758lbs. of green vetches were fed to six steers, representing an allowance of 136·65lbs. each per diem. The aggregate original weight of the steers was 5,499lbs., and their finishing weight 5,647lbs.; the daily individual increase was, therefore, represented by 1·37lbs. This crop of vetches supported, therefore, steers at the rate of 9·64 steers per acre for 18 days, and the equivalent steer-carrying capacity per annum would be 0·48 steers per acre—a slightly better carrying average than that of the corresponding pea crop. In addition to this the vetches stubbles were subsequently grazed over with sheep for two days at the rate of 21·28 sheep per acre, representing an equivalent of 0·12 sheep per acre per annum.

1912.—In 1912 the vetches were cut with a mower and put into the ensilage pits; hot weather had dried the crop off very considerably at the time, and the yield was only light, *viz.*, 1 ton 12cwt. 60lbs. to the acre. The stubbles were subsequently grazed over with sheep for 23 days at the rate of 19·46 sheep per acre, or the equivalent of 1·23 sheep per acre per annum.

## VETCHES GRAZED BY SHEEP.

In 1908, 1910, 1911, and 1913 the vetches were simply grazed off with sheep; full data concerning results recorded are shown below in Table XX.

TABLE XX.—*Showing Grazing Capacity of Rotation Vetches in 1908, 1910, 1911, and 1913.*

| Season.    | Number of Days<br>Grazed. | Sheep per Acre<br>for Number of<br>Days Grazed. | Equivalent Grazing<br>Value in Sheep<br>per Acre per Annum. |
|------------|---------------------------|-------------------------------------------------|-------------------------------------------------------------|
|            | Days.                     | Sheep.                                          | Sheep.                                                      |
| 1908 ..... | 38                        | 17·58                                           | 1·83                                                        |
| 1910 ..... | 40                        | 25·44                                           | 2·79                                                        |
| 1911 ..... | 19                        | 39·21                                           | 2·04                                                        |
| 1913 ..... | 13                        | 25·06                                           | 0·89                                                        |

These grazing results, although not very high, are consistently better than similar ones secured in rotation A for pease.

## WHEAT-BARLEY THREE-COURSE ROTATION.

In this rotation wheat is regularly preceded by one year's bare fallow, and followed by barley, i.e., one year's bare fallow and two cereal crops. This is a form of rotation with which we have been particularly successful on the College Farm, and which we think to be particularly well adapted to local conditions. It has been given a place among the plots of the Permanent Experiment Field only since 1911, and we are not, therefore, in a position to do more than quote the results of three seasons, one of which was abnormally bad, and the two others mediocre. These results are summarised below in Table XXI. It should be added that all plots had been treated as bare fallow in 1910.

TABLE XXI.—*Showing Returns from Wheat-Barley Three-Course Rotation, 1911-13—Plots 38, 39, and 40.*

| Season.    | Total<br>Produce<br>per Acre. |    |     |    | Grain<br>per Acre. |    |
|------------|-------------------------------|----|-----|----|--------------------|----|
|            | Tons cwt. lbs.                |    |     |    | Bush. lbs.         |    |
| WHEAT.     |                               |    |     |    |                    |    |
| 1911 ..... | 1                             | 19 | 3   | .. | 24                 | 12 |
| 1912 ..... | 1                             | 14 | 99  | .. | 22                 | 39 |
| 1913 ..... | 0                             | 11 | 43  | .. | 7                  | 12 |
| BARLEY.    |                               |    |     |    |                    |    |
| 1911 ..... | 2                             | 8  | 87  | .. | 43                 | 9  |
| 1912 ..... | 0                             | 19 | 100 | .. | 19                 | 41 |
| 1913 ..... | Stripped                      |    |     | .. | 9                  | 16 |

## FIVE-COURSE WHEAT-BARLEY-FORAGE CROP ROTATION.

This is a more complicated form of rotation, in which the land would come under bare fallow once in five years, crops following one another in the following order :—

|                   |             |                   |        |
|-------------------|-------------|-------------------|--------|
| First year .....  | Bare fallow | Fourth year ..... | Wheat  |
| Second year ..... | Wheat       | Fifth year .....  | Barley |
| Third year .....  | Forage crop |                   |        |

Obviously the success of this type of rotation will depend very largely on the extent to which it will prove possible to keep down undesirable weeds ; we anticipate that this end will be secured by heavy grazing. As was the case with the preceding rotation, this five-course rotation was given a place among the plots of the Permanent Experiment Field only in 1911, and it follows that at the time of writing the first period is short of completion by two years. We can therefore do no more than quote below in Table XXII. what results are available.

TABLE XXII.—*Showing Cereal Crop Results (1911-13) in Five-Course Rotation Wheat-Barley-Forage Crop.*

| Season             | Total<br>Produce<br>per Acre.<br>Tons cwt. lbs. | Grain<br>per Acre.<br>Bush. lbs. |
|--------------------|-------------------------------------------------|----------------------------------|
| SECOND YEAR WHEAT. |                                                 |                                  |
| 1911 .....         | 1 14 21 ..                                      | 15 17                            |
| 1912 .....         | 2 2 99 ..                                       | 27 58                            |
| 1913 .....         | 0 13 108 ..                                     | 6 48                             |
| FOURTH YEAR WHEAT. |                                                 |                                  |
| 1912 .....         | 1 2 93 ..                                       | 13 20                            |
| 1913 .....         | 0 11 70 ..                                      | 4 6                              |
| BARLEY.            |                                                 |                                  |
| 1912 .....         | 0 19 57 ..                                      | 20 26                            |
| 1913 .....         | Stripped ..                                     | 8 5                              |

## GENERAL CONCLUSIONS ON ROTATION PLOTS.

Before leaving this portion of the report we propose summarising the various conclusions that appear to derive therefrom. It must be fairly obvious, however, that if conclusions bearing on the rotation of crops are to carry any weight they must rest on a series of experiments extending over a far greater period of years than is usually necessary for other forms of agricultural experimental work. And in this connection the actual value of our conclusions may perhaps be questioned on the legitimate ground that at best they do not concern a period greater than nine years, and in most cases a much shorter period. We put these conclusions forward, therefore, for what they are worth, leaving it to time to justify or modify them according to circumstances.

(5) In this district, and those similarly situated, and in normal seasons, the net returns from a hay crop preceded by bare fallow are between 2s. 6d. and 3s. higher than those of a wheat crop cut for grain and similarly treated.

(6) In our experience the grazing capacity of land coming regularly under bare fallow and wheat in alternate years is still equal to about half a sheep per acre per annum, representing about 7s. 6d. per annum in the way of gross returns.

(7) In our experience—somewhat limited for the present—the mere fact of leaving land out of cultivation one year in three has not had the effect of materially affecting the grain yield of wheat; that same practice, however, appears to have led to an improvement in the hay yield of about 12 per cent.

(8) If a farm, in this district, be divided up into three equal parts, one-third of which would be treated as bare fallow, another third put under wheat, and another third grazed, the total average sheep-carrying capacity of such a farm would be about one sheep to the acre on the total area.

(9) If we take into consideration grazing values, the net returns from land carrying wheat once in three years are quite equal to those carrying wheat every other year ; and additionally, the improvement in the general fertility of the land must, in the course of time, prove very considerable.

(10) In our experience sorghum, when grown as a summer fallow crop, exeroises a depressing influence on the wheat crop that follows to the extent of 3bush. to 4bush. to the acre ; or if the crop be cut for hay, to the extent of 5cwts. to 6cwts. to the acre. It also appears to have the effect of lowering the bushel weight of the grain.

(11) In this district, and those similarly situated, it is only exceptionally that good crops of sorghum can be raised without irrigation on anything but land very light in texture.

(12) In good seasons the returns from wheat grown in regular rotation with other crops are quite equal to those from wheat grown regularly after bare fallow ; in bad seasons, however, returns from wheat after bare fallow are invariably superior.

(13) Turnips cannot be grown to advantage in this district as a rotation crop ; nor, indeed, in our view, in any district in which they cannot be raised successfully as a spring-sown crop.

(14) The average grain yield of Six-row barley, when grown in regular rotation, is practically double that of wheat similarly grown.

(15) Pease, when preceding wheat in rotation, must be both sown and grazed off early ; any neglect of these two points will lead to considerable reduction in the wheat yield. In the green state, pease offer excellent grazing for both cattle and sheep ; horses, however, do not appear to relish them.

(16) Good crops of kale cannot be raised in this district, except in seasons in which autumn rains are unusually early and heavy. When well grown this crop is of exceptionally heavy grazing value.

(17) In this district oats for grain form a far less reliable crop than Six-row barley.

(18) Vetches might, with advantage, be grown like pease in this district for grazing purposes, but for the exorbitant price usually charged for the seed.

*(To be continued.)*

## FEDERAL FRUIT COMMISSION.

### THE MINORITY REPORT.

Following on the majority report of the Royal Commission which was appointed by the Federal Government to inquire into the production and distribution of Australian fruit, a minority report, signed by Messrs. J. Thomson and S. Sampson, M's.H.R., has been presented to the Governor-General. The summary of the minority report printed below is taken from *The Register* :—

“The minority report states that the irrigation settlements on the banks of the Murray River supply overwhelming proof of the value of intelligent cultivation, and of scientific application of water to a responsive and highly fertilised soil. More than 12,000 acres was found under active cultivation at Mildura, with an annual output of upwards of £500,000. An import duty of 3d. per pound prior to 1907 on raisins is said to have given such a stimulus to the production of the fruit in the Commonwealth that production rapidly overtook the Commonwealth's demand. In a similar manner an increase in the duty of currants to 3d. had resulted in a surplus for export having been produced. Before then half the Australian requirements were imported.

### CO-OPERATION.

“A successful scheme of co-operation among the dried fruits producers of Mildura, in Victoria, and Renmark and Angaston, in South Australia, had resulted in an increase of production and a steady reduction of prices to retailers. There were also better methods of production, and the quality had improved. Wholesale fruits should therefore reach the consumer at a moderate price on the basis of the prices charged by the growers and wholesale merchants. The wholesale merchants paid 4½d. per pound for Three Crown currants, and sold them to the retailers for 4½d. These prices, operated under the co-operative list, returned a reasonable profit to the growers, and proved that the protection at present afforded was necessary to ensure the stability of the industry. No undue advantage of the tariff was taken by the association of growers. Reference is made to the inadequate railway service, and the opinion is expressed that a more speedy service and special fruit trains would lead to considerable advancement in the prosperity of Mildura and similarly situated settlements.

## WORK OF COMMISSION.

"The statements in the majority report of the events which, it was alleged, were largely responsible for the appointment of the Commission were, in the opinion of the minority, an unnecessary interpolation, did not serve the purpose of the inquiry, and partook more of the character of a political party manifesto than an official document. No direct evidence was furnished to the Commission that there was any opposition to the prosecution of its inquiries. On the contrary, the support received from associations and others in Tasmania and other States should be acknowledged. One witness only, Mr. W. D. Peacock, acting on legal advice, declined to reply to certain questions, and claimed that the inquiry into jam manufacturing was beyond the scope of the Commission. His contention was subsequently upheld by the Commonwealth Crown Department. In no other instance did any one refuse to answer questions, or fail to produce a document when required. The case cited in the majority report was based on hearsay and not on direct evidence, and was rebutted by an equally reputable witness, Mr. W. Cuthbert, orchardist, of Franklin, Tasmania.

## QUESTION OF COMBINE.

"It was found by the minority of the Commission that the fruit trade of Tasmania was handled by certain firms who worked in conjunction in order to secure economy and efficiency in administration. By their united efforts they had been enabled to make large contracts over a specified period with various shipping companies, with the result that the export freight on fruit was lower from Tasmania than from any other State. With reference to the statement in the majority report in regard to Henry Jones Co-operative, Limited, and Henry Jones and W. D. Peacock & Co., shipping agents and jam manufacturers, of Tasmania, Messrs. Sampson and Thomson state that how far financial influence was exercised by one firm over another they were not competent to say, as their powers of inquiry did not extend to jam manufacturing. The position was that the Tasmanian agency firms referred to, whatever might be their financial relations to other firms, had reduced the agency charge and the cost of shipment of fruit below those which ruled on the mainland. The minority report expresses disagreement with the statement made in the majority report that heavy rates of interest were charged for orchard requisites. Its inquiry discloses that ordinary bank rates were charged on loans, and that advances on account of fruit were made free of interest from the time that the fruit was received as security. The minority were unable to find that the growers suffered any disability in the purchase of their orchard requisites.

"Advantages which it was claimed in the majority report would accrue to growers under Government departments were stated by the minority to be purely problematical, as there was no evidence to substantiate such claims.

In support of this contention, the evidence is quoted of Mr. Pope (Manager of the State Department of South Australia) that the minimum charges made by his department were 4s. 1½d., and the evidence of Henry Jones showed that the Tasmanian charges were 3s. 11d. Notwithstanding the higher charges made, the South Australian department showed a heavy deficiency.

"It was found by Messrs. Thomson and Sampson that there is ample scope for irrigation by individual effort, apart from the larger State-owned schemes. Satisfaction is expressed at the action taken by the Department of Trade and Customs in communicating with the various State Governments in dealing with the previous recommendations."

---

## DECIDUOUS TREE PLANTING.

---

[By W. R. LEWIS, Hon. Secretary Berri Agricultural Bureau.]

The following paper on the planting of deciduous trees was read by Mr. W. R. Lewis, Hon. Secretary of the Berri Branch of the Agricultural Bureau, at a meeting held on May 9th :—

The planting season will shortly be upon us, and it may be that a few hints bearing upon the subject of preparation of land and planting of trees may cause intending planters to think well over the matter, not only as to what they shall plant, but how, when, and where. In the first place we must conclude that the land has been well cleared, the roots got out, and, where needed, graded. This is very important, as if the land is badly graded there will always be a difficulty in irrigating that will not only add to the cost of watering, but will injure the orchard, as some trees will get too much water and some not sufficient. To grade easily one must have had clearing well done; it is not conducive to good work to be constantly hitting roots with the buckscraper. The same applies to ploughing, which also must be well done; the deeper the better. The firmer the surface soil, the greater the need to plough deeply. On loose sandy soil where the roots will have no difficulty in going down, deep ploughing is not of such vital importance. It is, of course, better to plough even sandy loose soil well, and give the sun and air a chance to act upon it. When the soil is hard and the subsoil firm, every

effort should be made to loosen it deeply and thoroughly to the depth the trees require to be planted ; deeper if practicable. Where the soil is really hard use gypsum. As this is somewhat expensive give a good dressing around where each tree will be planted, and allow the remaining portion to wait. It is very little use planting on the hard clay patches, such as we have on the eastern part of this settlement, until one can, by some means, loosen up the soil. Lime, stable manure, leaf mould all help, but none of them are equal to a good application of gypsum. The land can be worked cheaper and better before planting than afterwards, so, if possible, do all this work before pegging out for the trees. Ploughing strips of land for planting is only allowable when time will not permit of any other method.

When the land is well ploughed and worked down, if the orchardist has had no experience he should get someone who has to lay out the orchard. Whether one adopts the square or septuple plan is not, to my mind, a matter of great importance. I personally favor the square, as I think it gives more room and convenience in cultivating, and if the trees are planted 20ft. apart when they are in full bearing they will be taking as much from every acre as one can reasonably expect. If one plants thickly one will have to manure heavily, and the sun's beneficial action on the soil and plants will be to a degree checked. If the double pegs are used planting will be simplified, as it will be necessary only to drop the planting board into position, and the cut in the centre of the board will give, not only the line of the trees, but the ground level at the same time. If the tree is held to the board at about the same level as it stood in the nursery, when the hole is filled in the tree should be in line, and at the proper depth. This is more important with citrus than deciduous trees, but is worth observing in all. There is nothing to be gained by deep planting. Holes large enough to allow of the roots spreading should be quite sufficient. The ground around the holes should be loose enough for the young roots to penetrate. Cut back the young trees to form a low crown ; this will later on be found an advantage, as in gathering a crop one man will pick from the ground probably as much as three men on stepladders. When it comes to spraying and fumigating there is a great advantage in having fairly low trees. Reserve the best land, rich sandy loam well drained, for citrus trees. Good land is also required by peaches, and they must have good drainage ; anything approaching seepage will soon ruin peach trees. In this respect they are less hardy than apricots ; but these also require good drainage, but do fairly well in soils not quite so rich. Sultanas will stand a fair amount of moisture, almost amounting to seepage ; but, like all other fruits, will do better if the land is in perfect order. Experience has proved that the sultana will stand more salt than any other fruit-bearing tree or vine. Prunes seem to do best on the heavier soils, and may be planted in the lower situations. Apples, also, do well on the fairly heavy river lands, in fact, the best apple trees I know in Renmark, trees that have borne regular and heavy crops for

years past, are in a soil that can only be described as a heavy clay. Pears will also grow on heavy soils, and even on lands bordering on seepage. Trim the roots before planting, to remove all damaged wood and bruised bark, as the young roots start better from around cleanly cut surfaces than they do from a bruised and damaged one. Spread the roots evenly, with, for preference, a downward tendency at the extremities, and press the soil firmly. If one can apply water to the trees when planting or soon after, it will set the earth around the roots better than can be done by any other means.

Certain classes of trees thrive best on certain soils ; one may do best in light sandy soil, another in loam of a light nature, a third may do best in a heavy soil, and some trees thrive in heavy clays when once established. It is, therefore, advisable to carefully study the nature of the land, the class of soil, drainage, &c., and then plant the trees most likely to succeed in each particular. Quinces are, of course, only saleable locally, so cannot be planted to any extent, but a tree or two may be planted in a wet low situation, on the edge of the waterhole say, and will be found to thrive and bear well. Almonds should have the driest positions, and will thrive on somewhat indifferent soil, and, with a little assistance in the matter of irrigation, should be profitable. Walnuts seem to do best on a fairly dry soil having good drainage, and, I think, this variety of nut should have a fairly good future before it on these Murray lands. Care should be taken to plant a variety that will stand our hot spells, as the English walnut suffers at such times. The French walnut has the reputation of standing heat very well.

Orchard, Near Clare.

## SOUTH AUSTRALIAN BARLEY IN ENGLAND.

[Report by TRADE COMMISSIONER.]

A few months back, at the instance of Mr. Geo. R. Laffer, M.P., the Director of Agriculture secured some fair average samples of barley from four parts of the State. These were forwarded by the Minister of Agriculture (Hon. T. Pascoe, M.L.C.) to the Trade Commissioner in London for the purpose of ascertaining whether a profitable market existed or was likely to occur there. The then Trade Commissioner, Mr. A. E. M. Norton, subsequently forwarded the following report :—

“ Unlike wheat and oats, for which there is a demand all the year round, barley is a seasonable article, and is only required during the malting season. The season in the United Kingdom commences early in September and ends in May, accordingly any barley arriving in this country between seasons has to be held in store until the season opens. Due to my connection with the Brewers' Exhibition, I am personally acquainted with most of the leading barley merchants in the United Kingdom. Immediately I received the post samples, I submitted small samples to a few of the best firms, with the following results :—

“ *Sample No. 1 : Barley, South-East.*—Shows the finest quality, and would probably realise 32s. to 38s. per quarter (448lbs. = 4s. to 4s. 9d. per bushel).

“ *Sample No. 2 : Barley, South.*—This sample is from 1s. to 2s. per quarter (1½d. to 3d. per bushel) inferior to No. 1 sample, and shows the presence of weevil, which would necessarily lessen the value if the bulk were similar.

“ *Sample No. 3 : Barley, Kangaroo Island.*—Is inferior to the other two samples of Chevalier type, and should be worth from 28s. to 34s. (3s. 6d. to 4s. 3d. per bushel).

“ *Sample No. 4 : Barley, Lower North.*—This is usually described as “ brewing barley,” and would come into competition with shipments from the Pacific Coast and the Mediterranean, and would necessarily depend on the supplies obtainable from these sources and their relative prices. Taking an average season, however, this sample would sell at from 26s. to 30s. per quarter (3s. 3d. to 3s. 9d. per bushel).

“ The prices mentioned are landed terms. If you estimate the cost of landing and storage at 1s. per quarter, or 1½d. per bushel, it will give approximately the c.i.f. value. In regard to the first three samples, the prices will, to a very great extent, depend upon the English harvest ; that is to say, if the English harvest is a favorable one then the lower prices will

obtain ; but if the English harvest is a poor one, there is the probability of obtaining the higher prices. I could, of course, keep you well posted with the latter information when the harvest results in this country are known.

#### HARVESTING.

" No. 1 : *South-East*.—This sample is well harvested, and there are few seasons in which such quality would fail to realise 35s. per quarter (4s. 4½d. per bushel) landed terms.

" No. 2 : *South*.—This sample has been badly managed, being very broken at the ends in thrashing, which lessens its value considerably.

" No. 3 *Sample*.—The above remarks will apply in a lesser degree.

" No. 4 *Barley*.—This sample appears to be well managed, and not injured in any way in thrashing.

" The defects mentioned are easily remedied, and it would be well to point out to the producers the danger of thrashing barley too closely, so as to prevent injury to the grain, which, if broken at the ends, results in the broken grains becoming mouldy when the barley is on the malting floors. Generally speaking, all the samples are useful quality, and would always find a market in the United Kingdom ; but, as previously stated, values are governed mainly by the nature and condition of the English market. If it is decided to send any trial shipments, I would strongly recommend that they be sent direct to Bristol, as this is, without doubt, the best port in the United Kingdom for barley."

## PEACH LEAF CURL FUNGUS.

(*Exoascus deformans*, Fuckl.)

### FURTHER TESTS WITH FUNGICIDES.

By GEO. QUINN, Horticultural Instructor.

These trials were begun at the Government Experiment Orchard at Blackwood in 1910, continued in 1912, and repeated in 1913. The respective results for the two first-named years' work were published in the *Journal of Agriculture* for August, 1911 and 1913. The trials were not begun because effective—i.e., commercially effective—remedies were not known for the prevention of this fungus, but in an endeavor to ascertain which of those put forward were the most consistently effective and economical, and to place

any knowledge gained from these investigations upon a more exact basis than had existed hitherto. Since commencing this work several new fungicides have been brought forward, and these have been included. Until last season those under trial consisted of—

Bordeaux mixture, Burgundy mixture (copper-soda), Woburn Bordeaux mixture, Bickford's Bordeaux powder, lime sulphur compound, copper sulphate solution.

These were used in the following proportions :—

*Bordeaux Mixture.*

|                                                                               |          |
|-------------------------------------------------------------------------------|----------|
| 1lb. copper sulphate (bluestone), expressed in commercial quantities .. . . . | 4lbs.    |
| 3lb. quicklime, expressed in commercial quantities .. . . .                   | 3lbs.    |
| 10galls. of water, expressed in commercial quantities .. . . .                | 40galls. |

*Burgundy Mixture (Copper-Soda).*

|                                                              |          |
|--------------------------------------------------------------|----------|
| 1lb. copper sulphate, equalling .. . . .                     | 4lbs.    |
| 1lb. 14ozs. carbonate of soda (crystals), equalling .. . . . | 7½lbs.   |
| 10galls. water, equalling .. . . .                           | 40galls. |

*Bickford's Bordeaux Powder.*

|                                          |          |
|------------------------------------------|----------|
| 1oz. Bordeaux powder, equalling .. . . . | 1lb.     |
| 3½galls. water, equalling .. . . .       | 50galls. |

*Copper Sulphate Solution.*

|                                           |          |
|-------------------------------------------|----------|
| 4ozs. copper sulphate, equalling .. . . . | 1lb.     |
| 10galls. water, equalling .. . . .        | 40galls. |

*Lime Sulphur Compound.*

|                                              |          |
|----------------------------------------------|----------|
| 3lbs. flowers of sulphur, equalling .. . . . | 15lbs.   |
| 3lbs. quicklime, equalling .. . . .          | 15lbs.   |
| 10galls. water.. .. .                        | 50galls. |

*Woburn Bordeaux Mixture.*

|                                                                |                                                          |
|----------------------------------------------------------------|----------------------------------------------------------|
| 10½ozs. copper sulphate, equalling .. . . .                    | 6lbs 6½ozs.                                              |
| Dissolved in 1gall. water, equalling .. . . .                  | 10galls. water.                                          |
| 5ozs. quicklime, to make 9galls. clear limewater, equalling .. | 3lbs quicklime, making<br>90galls. clear lime-<br>water. |

In the preparation of these spraying compounds the usual methods were followed; the bluestone for the Bordeaux and Burgundy mixtures being dissolved in small volumes of water in one vessel and the lime and soda in others. They were each diluted with more water before the blending was entered upon. The Bordeaux powder was liquified in a small vessel of water before being stirred into the spray pump tank. The copper sulphate solution needs no explanation, but the strength used scarcely dyes the water the characteristic blue color of this salt. The lime sulphur compound was made in the usual manner by boiling the two ingredients together, the formula followed being one published by the Department of Agriculture in a neighboring State. The Woburn Bordeaux mixture differs from the standard form in common use here, in so far that the excess of lime contained in milk of lime is avoided by using clear limewater until drops of a solution of potassium ferrocyanide fail to give any visible reaction in the shape of a brownish discoloration. Mr. Savage, the orchardist, who carried out these trials with his usual carefulness for detail, when commenting on this formula, states—"When using 5ozs. of quicklime to 10galls. of water, 11galls. of clear

limewater were required to neutralise the solution of copper sulphate. A week later 12galls. of clear limewater were needed to effect the neutralisation of the same quantity of bluestone solution, even when 7ozs. of quicklime were used." This may be due to the variable quality of the quicklimes, either owing to the proportion of actual lime (calcium oxide) present originally varying, or the reversion of a percentage of it again to the carbonate through exposure. We are assured, however, by analysts that the samples of commercial quicklimes upon the local market are extremely variable in their essential constituent.

The trees used in these tests consist of a block of the variety Elberta, known to be notoriously susceptible to the attacks of the curl leaf fungus. They are now evenly-grown open-centred trees in good bearing, having reached a size favored by commercial peach growers in the non-irrigated portions of this State.

The spraying began on August 12th, whilst the buds were as yet apparently quite dormant. On this date the first application was made to those treated with the Bordeaux powder and the lime sulphur compound. Those trees receiving all of the other fungicides were first sprayed on the following day, viz., August 13th. The second spraying for those designed to receive more than one was applied on August 19th to the Woburn Bordeaux, Bordeaux powder, and lime sulphur rows; but rain setting in and unsuitable weather prevailing, the second spraying could not be given to the copper sulphate solution, Burgundy and Bordeaux tests, until August 23rd. This is one of the unforeseen and unavoidable circumstances which may arise and prevent the possibility of instituting an exact comparison between field experiments. In this case, however, the proportion between the diseased leaves on those rows sprayed before and after the delay through rain does not indicate any definite advantage or disadvantage arising therefrom.

One striking fact indicated by every fungicide tested in these trials is the necessity for two sprayings being given each season to secure the repression of this fungus in localities possessing a similar set of climatic conditions to those prevailing at Blackwood.

Another fact which each succeeding season's growth has accentuated is that dressings of ferrous sulphate applied to the soil, such as have been used by us in these trials, are quite valueless in assisting the peach trees to resist the attacks of the curl leaf fungus. Although the proportion of diseased to healthy leaves carried by the trees whose roots have been thus top-dressed has not been calculated, the rising figures given of the diseased leaves for 1910, 1912, and 1913 would appear to indicate the attack of the fungus is increasing in its virulence on these particular trees.

The Bordeaux and Burgundy mixtures, the Bordeaux powder, and the copper sulphate solution have now been tested over a period of three seasons,

and the table indicating their comparative protective powers, in the shape of the average number of diseased leaves borne per tree per year, is given herein. This table bears out the consistently good work attributable to the Burgundy or copper soda compound; and indeed one spraying with this has exceeded in value two sprayings of all other compounds or mixtures excepting the standard Bordeaux. Although only under trial as yet, for a single season the lime sulphur compound is distinctly promising as a means of preventing the ravages of this fungus.

TABLE SHOWING DETAILED RESULTS OF TESTS IN 1913.

| Test. | Tree. | Spray Compound Used.             | Dates of Spraying. | Diseased Leaves collected from each Tree on Oct. 24th, Dec. 2nd. | Total. |
|-------|-------|----------------------------------|--------------------|------------------------------------------------------------------|--------|
| 1     | 1     | Copper sulphate solution . . . . | Aug. 13, 23        | 303                                                              | 650    |
|       | 2     | " " " " " " " "                  | " "                | 68                                                               |        |
|       | 3     | " " " " " " " "                  | " "                | 279                                                              |        |
| 2     | 4     | " " " " " " " "                  | August 13          | 266                                                              | 1,521  |
|       | 5     | " " " " " " " "                  | " "                | 313                                                              |        |
|       | 6     | " " " " " " " "                  | " "                | 942                                                              |        |
| 3     | 7     | Burgundy mixture . . . . .       | Aug. 13, 23        | 29                                                               | 33     |
|       | 8     | " " " " " " " "                  | " "                | 4                                                                |        |
|       | 9     | " " " " " " " "                  | " "                | 0                                                                |        |
| 4     | 10    | " " " " " " " "                  | August 13          | 15                                                               | 90     |
|       | 11    | " " " " " " " "                  | " "                | 61                                                               |        |
|       | 12    | " " " " " " " "                  | " "                | 14                                                               |        |
| 5     | 13    | Bordeaux mixture . . . . .       | Aug. 13, 23        | 10                                                               | 77     |
|       | 14    | " " " " " " " "                  | " "                | 45                                                               |        |
|       | 15    | " " " " " " " "                  | " "                | 22                                                               |        |

## THE MEDICINE SHELF.

[By F. E. PLACE, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.]

From time to time inquiries come in from farmers isolated in the back blocks as to what medicines should be kept on hand for emergency use, so that a few pages may be usefully devoted to naming those which have been found to be generally useful and fairly safe to administer.

First, we will give a list, with the quantity suggested to be kept, and then a brief description of their uses. The doses will be for an adult horse, and should be reduced to half for a three-year-old or a quarter for a yearling or under. For cattle half as much again as for a horse, with similar reductions for age. For sheep, a quarter of the cattle dose. For pigs, according to age and size.

### LIST OF DRUGS.

Aconite, tincture, loz.; alcohol, methylated spirit, or gin, 1qt.; ammonia, ordinary household,  $\frac{1}{2}$ pt.; ammonia, carbonate or rock, loz.; antimony tartrate,  $\frac{1}{4}$ lb.; arnica tincture, loz.; arsenic, Fowler's solution, 1lb.; belladonna, tincture, loz.; benzine, 1pt.; boracic acid, 1lb.; calendula, tincture, loz.; camphor,  $\frac{1}{4}$ lb.; charcoal, 1lb.; chloral hydrate, loz.; copper sulphate (bluestone), 1lb.; eucalyptus oil, loz.; iron phosphate, syrup, 1lb.; glycerine, 1lb.; iodine, resub. (pure),  $\frac{1}{2}$ oz.; oil, raw linseed, olive, and castor, each 1pt.; magnesium sulphate (Epsom salts), 14lbs.; peppermint essence, loz.; nux vomica, tincture, loz.; nitrate of potash (saltpetre), 4ozs.; permanganate of potash (sometimes called Condry's crystals), loz.; soap, hard and soft, each 1lb.; soda bicarbonate (baking), 1lb.; soda (washing), 1lb.; soda, hyposulphite (photographer's hypo.), 1lb.; sulphur, flowers of, 1lb.; tar, Stockholm, 1lb.; turpentine, 1pt.; treacle or honey, 1lb.

The drugs in this list do not by any means form a complete medicine chest, but they are sufficient to afford ready first aid help to an animal; and it is better to have a few things handy, and know how to use them, than to have a drug store without the knowledge.

### USES OF THE DRUGS.

**ACONITE.**—Dose, 10 to 15 drops. Small doses such as these will be found more efficacious than larger ones, and may be given at the onset of any disease likely to lead on to inflammation, such as colic or cough; a dose three times a day is, as a rule, sufficient; but if the pain is acute, the pulse very small and quick, then a dose may be given as frequently as once an hour, mixed with a little honey, and put on the tongue or teeth. In chronic

conditions such as laminitis and founder, a dose morning and evening suffices ; but should be continued for a month or so. One part of tr. aconite to 10 of glycerine forms a very useful liniment to a part that is acutely painful.

**ALCOHOL.**—Dose, a teacupful to half a pint. It is useful when there is exhaustion ; also, mixed with soothing things like peppermint, stimulates organs like the bowels and kidneys. It also reduces temperature in fevers, especially of a low influenza type. Methylated spirit is cheap, and good enough for animals ; but gin or brandy or whisky may be used instead. Where none is obtainable, coffee may well be substituted, a quarter pint to a pint, given ground and all. Methylated spirit is an excellent dressing for wounds, especially as a solvent for arnica, iodine, and so forth. Where cooling applications are wanted, such as for sprained tendons, it is one of the best, mixed with water half and half.

**AMMONIA.**—Dose, one teaspoonful mixed with honey or cold water is an excellent stimulant in prostration. In colic or stoppage of the water, it may be repeated if necessary every twenty minutes. A teaspoonful of the rock ammonia with honey is very useful in colds, coughs, &c. Equal parts of ammonia, olive oil, and turpentine make an excellent embrocation. The fumes of ammonia are also a good disinfectant.

**ANTIMONY TARTRATE** (tartar emetic).—Dose for fevers, one flat teaspoonful ; for worms, one heaped teaspoonful ; to make a dog sick, a pinch in a little warm water. Useful twice a day in low fevers, such as influenza, especially if there is a rash about the lips. For blood and other worms, it is given daily for some days alone or mixed with drugs, such as santonine or iron. It or black antimony generally forms part of condition powders.

**ARNICA, Tincture.**—Dose, internally 10-15 drops with honey ; externally, 1-20 methylated spirits or water. Internally in cases of bleeding, as after foaling ; externally for strains, bruises, &c., and very useful as a dressing after castration.

**ARSENIC** (Fowler's solution.)—Dose for worms, two tablespoonfuls ; tonic, one tablespoonful ; to reduce fever, one teaspoonful.

Arsenic is a drug that cannot be played with, and Fowler's solution is a ready means for accurate dosage, hence it is recommended ; its name is not connected with a well-known South Australian firm, but derived from its inventor.

For bloodworms, two tablespoons once daily for a fortnight, then stop for a fortnight, and repeat for second fortnight ; in severe cases it is well to give a teaspoonful (about 30 grains) of sulphate of quinine as well ; both drugs will be taken in food. In low lingering fevers, such as strangles, influenza, &c., arsenic has a better effect than aconite, and a teaspoonful of this preparation

can be given two or three times a day. When an animal is recovering only slowly from any disease a tablespoonful one or twice a day for some days will act as a tonic. If arsenic is to be used as a caustic to a large gland or similar condition, a paste may be made of an arsenical dip, such as Cooper's; but great care must be used when applying such, as absorption may occur and poisoning result.

One of the best antidotes for arsenic is large quantities of water from the trough the smith tempers iron in.

**BELLADONNA**, Tincture.—Dose, 10-15 drops. Used similarly to aconite; but in cases of congestion, when the pulse is full and the eyelids dark-colored, also for sore throat, milk troubles, and scouring from bilious diarrhoea. Externally, 1-10 in glycerine to painful udders and similar painful swellings.

**BENZINE**.—One tablespoonful in water as a stimulant; in oil for worms. Externally (pure), an excellent wound dressing, especially for sluggish conditions, such as fistula, quittor, &c. The purse may be wiped with it before castration; 1-5 oil for mange, &c.

**BORACIC ACID**.—One of the best dry dressings for all kinds of wounds; mixed seven parts with one part sulphur is quite as good for animals as iodoform, and very much cheaper; one to four glycerine makes a good ointment. For want of anything better a heaped teaspoonful may be given in windy colic or to a bloated cow.

**CALENDULA**, Tincture.—One to 20 methylated spirit externally to cut wounds or sluggish healers, such as broken knees. Also for damage in foaling and the like.

**CAMPHOR**.—Dose, a flat teaspoonful with honey two or three times daily for cough, sore throat, &c., similarly for water troubles, especially pizzle disease in wethers, for which dose is a pinch. Externally, 1-4 glycerine or lard forms very soothing ointment, especially for recent cracked heels.

**CHARCOAL**.—Dose, two or three heaped tablespoonfuls for windy colic, bloating, &c.; one tablespoonful twice daily in food for earth or dung eating, indigestion, &c. Externally, 1-4 glycerine is a good wound dressing for broken knees, &c. Antidote for many poisons, such as arsenic, phosphorus.

**CHLORAL HYDRATE**.—Dose, 1oz. Allays pain, given in half pint water, or with honey as ball, or injected as enema with water or milk for severe colic, or foaling pains, or to allay spasms in diseases like lockjaw or fits. Should not be repeated under six or eight hours.

**COPPER, SULPHATE** (Bluestone).—Dose, flat teaspoonful once or twice daily in food, as tonic or for worms; often given as pickled wheat. Externally, a solution is healing and astringent; used for proud flesh, fly blow, &c.; 1-2 glycerine caustic for proud flesh. Used pickling strength, half to 2 per cent is useful as a general disinfectant.

**EUCALYPTUS OIL.**—Dose, 10-15 drops with honey for coughs, colds, sore throat, colic, water trouble. This small dose is far more effective than the large doses generally given, which are anything but safe, and often set up serious trouble. For steaming for colds, strangles, &c., one teaspoonful is quite enough. Externally, 1-20 methylated spirits or 1-10 glycerine for sprains, wounds, &c.

**IRON PHOSPHATE, Syrup (Parrish's Food).**—Dose, one or two tablespoonfuls with honey or plain. A good general tonic, and specially useful in chronic cases of dry bible; may be given two or three times a day for a week or two; also recommended after diseases like strangles as a pick-me-up.

**GLYCERINE.**—Dose, one tablespoonful, plain or with other drugs, such as belladonna or tar, for coughs, colds, &c. Of some use in broken wind. As an injection 4ozs. alone or with soapsuds is extremely valuable in all cases of stoppage. A very useful vehicle for most drugs, as it can be smeared on the tongue. Equally useful to hold them for external application, especially for udder troubles.

**IODINE, Pure.**—One dram (as much as will lie on a shilling) to a pint of methylated spirits forms the most useful all-round wound dressing. One tablespoonful of this mixture may be given with honey or glycerine two or three times daily in inflammation of the lungs. One part iodine, four parts pure carbolic acid form a dressing for lumpy jaw.

**OIL, RAW LINSEED.**—Dose, 1-2 pints. A good general purgative for horses or cattle. Dose, 1-2 tablespoonfuls makes a tonic food useful in broken wind.

**OIL, OLIVE.**—Dose, similar to linseed; 20 parts olive oil, four methylated spirits, two ammonia, one camphor make an excellent liniment which may also be used internally in one or two tablespoon doses for stoppages, coughs, &c.

**OIL, CASTOR.**—Dose, quarter-pint to half-pint, with or without other oil, is a useful purge for horse, and, unlike the others, of service in sand. Good dressings for wounds, keeps off flies and insects. Useful, with or without glycerine, as enema.

**MAGNESIUM SULPHATE (Epsom Salts).**—Best purge for cattle. Dose for them,  $\frac{1}{2}$ lb.-1lb. in warm water, coffee, or beer. A dessertspoonful of ground ginger, pepper, or mustard mixed with this lessens the griping.

For horse, 4ozs. once or twice in mash or water are good laxative; 2ozs. once or twice a day for a few days act similarly; 1oz. two or three times a day in food, drink, or with honey is one of the best fever medicines possible.

In lockjaw, get horse to drink as much as possible daily, probably about 8ozs.; 2-4ozs. may be given each Saturday evening in food or drink with advantage in most cases.

Externally, 4ozs. in half-pint of water and half-pint methylated spirits form cooling lotion for sprains, &c. Epsom salts form the basis of many condition powders.

**PEPPERMINT, Essence.**—Dose, 20-25 drops with spirit form one of the best remedies for stoppages, and may be repeated in half an hour if necessary. If essence is not at hand a wineglassful of peppermint cordial may be substituted, or  $\frac{1}{4}$ lb. strong peppermint lollies crushed up and dissolved.

**NUX VOMICA, Tincture.**—Dose, 10-15 drops morning and evening when dung and water are not quite what they should be, or alternately with ammonia in stoppage, in which case several doses may be given in hourly succession. For dry bible and similar symptoms, four or five doses a day, especially if once or twice a pint of yeast is also given. Alternately with charcoal for dung eating; alternately with camphor when water is dark and thick.

**NITRATE OF POTASH (Saltpetre).**—Dose, 1-2 teaspoonfuls. These small doses are more effective than the large ones often used. Give two or three times a day for feverish conditions, such as coughs, colds, influenza, and strangles, or when urine is thick and white and scanty; 2ozs. to a pint of methylated spirits and water form a good cooling lotion for sprains, &c.

**PERMANGANATE OF POTASH.**—A good general disinfectant. As much as will lie on sixpence to 2galls. of warm water makes excellent douche after foaling, cleaning, &c. In cases of blood poisoning as much as will lie on threepenny piece may be given internally; but not to in-foal mares or cows in calf. A pint of a port wine-colored solution may be given for phosphorus poisoning.

As a dressing for wounds this drug is usually used too strong. It should not be used with soap solutions.

**SOAP, Hard or Soft.**—Dose, 1-2ozs. as a ball or dissolved as suds are most useful in cases of stoppage, indigestion, &c. Thick suds externally are good dressing for lice, mange, &c., especially when followed by benzine one part, oil five parts. Hot soapsuds are one of the best dressings, used as a fomentation for udder troubles; 2galls. or 3galls. of warm soapsuds, with or without glycerine, are a good enema, and should always be used in cases of stoppage.

**SODA, BICARBONATE (Baking).**—Dose, one teaspoonful to  $\frac{1}{4}$ lb. The small doses once or twice daily in indigestion, dung eating, or stomach worms; 1-2ozs., with or without other drugs, in water or spirit for colic, stoppage, etc.;  $\frac{1}{4}$ lb. doses in milk or water for overgorging with wheat. A pinch to a pint of warm water to swab out a mare before service to ensure foal. As a dry dressing for wounds, thrush in the frog, &c.

**SODA (Washing).**—May be substituted for baking soda, but is not so good ; the doses should be only half the former. A handful of soda in 3galls. or 4galls. of warm water is excellent as an antiseptic for use after foaling, cleaning, &c., or for wounds. Dry soda powder may be used on proud flesh with advantage, also for thrush, canker, &c.

**SODA HYPOSULPHITE (Photographers' Hypo).**—Dose, 1-2ozs. Given in water for windy colic, bloating, &c. ; 1oz. twice daily in food or water in blood poisoning, strangles, influenza, after foaling, &c. The crystals may also be applied to sluggish wounds.

**SULPHUR.**—Dose,  $\frac{1}{2}$ oz. in food once daily as preventive for strangles, influenza, &c. Twice daily for constipation, indigestion, &c. Dry dressing for wounds ; keeps off flies.

**TAR, STOCKHOLM.**—Dose, one dessertspoonful. With or without honey on tongue or teeth in colic or stoppage, especially in coughs, colds, strangles, influenza, &c., when it is of greater use if a rag dipped in tar is wrapped round the bit and left in the mouth for an hour or two.

As a general wound dressing with or without other drugs. With wool or pitch forms permanent bandage in breakdown of tendons, or instead of blister, being the more beneficial.

**TURPENTINE.** (Ordinary Painters' Turps, not Spirit of Turpentine).—Dose, 1-2 tablespoons. *Always well diluted with other oil and kept well shaken up.* Useful in colic, stoppage, &c., and for worms, especially the long round ones ; or, mixed with a quart of warm milk, as an injection for the whipworms in the hinder gut. As ingredients of liniments or alone to stimulate skin. Good dressing for wounds or maggots.

**TREACLE or HONEY** in 1-lb. or 2-lb. doses are useful in sand, dry bible, etc., and as vehicles for other medicines.

### THE MOST IMPORTANT DRUG

is *commonsense*, and should be mixed with any or all the foregoing, for without it they will do more harm than good, and often it will be an effectual substitute for any of them.

## ANALYSES OF FERTILISERS.

The following are results of analyses made by the Government Analyst (Mr. W. A. Hargreaves, M.A.) of further samples of fertilisers taken by inspectors under the Fertilisers Act since the beginning of the year:—

| Name of Firm and Fertiliser.               | Phosphate.          |                     |                     |                     | Acid Soluble.       |       | Total Phosphoric Acid, calculated as Tricalcic Phosphate. |      | Nitrogen.           |      |
|--------------------------------------------|---------------------|---------------------|---------------------|---------------------|---------------------|-------|-----------------------------------------------------------|------|---------------------|------|
|                                            | Water Soluble.      |                     | Citrate Soluble.    |                     | Vendor's Guarantee. |       | Result of Analysis.                                       |      | Vendor's Guarantee. |      |

**GEO. QUINN, Inspector of Fertilisers.**

## VINEYARD AND ORCHARD PRODUCTION, 1913-14.

### INCREASED ACREAGE, DECREASED VINTAGE.

The Government Statist (Mr. L. H. Sholl, C.M.G.) has issued the official return of yields of the vineyards and orchards of South Australia for the past season. The acreage under vines continues to show a steady increase, but in comparison with the previous season's output, which was a record, there was a considerable falling-off in the yield of grapes and the quantity of wine made. The yield of grapes was 35,487 tons, or 1·63 tons per acre of the vines of bearing age, against 42,605 tons or 2·00 tons per acre for the previous season. A total of 18,572 tons were used for winemaking, the quantity of wine made amounting to 2,759,665 gallons, the figures for 1912-13 being 3,974,838 gallons. Of the quantity made, probably 1,215,173 gallons will be distilled. Of currants 49,170 cwt. were dried, being a decrease of 3,038 cwt. Raisins.—Sultanas, 16,508 cwt.; decrease, 67 cwt., all other, 19,040 cwt.; increase, 367 cwt.

#### STATEMENT OF AREA AND PRODUCTION OF VINEYARDS FOR THE FIVE SEASONS, 1909-10 TO 1913-14.

#### EXPORTS OF WINE.

A substantial export trade in wine and brandy made from wine is carried on with the other Commonwealth States; but as it is not recorded, the following statement is confined to the exports of wine to countries beyond the Commonwealth.

| Wine.         | Oversea Exports for Years— |         |         |         |         |
|---------------|----------------------------|---------|---------|---------|---------|
|               | 1909.                      | 1910.   | 1911.   | 1912.   | 1913.   |
| Gallons ..... | 520,269                    | 449,673 | 585,603 | 461,414 | 427,360 |
| Value .....   | £ 53 ,225                  | 48,414  | 66,617  | 53,763  | 46,617  |

For the years 1908 and 1909 (the last two years for which complete inter-State records are available) the exports to other States were respectively 440,088 and 525,409 gallons. Since 1909 it is estimated that the inter-State exports have ranged from 520,000 to 570,000 gallons annually.

On this estimate the exports oversea and inter-State for 1913 were 997,360 gallons, with an average annually for the last five years of 1,026,178 gallons.

#### VALUE OF PRODUCTION.

The following statement shows the estimated value of vineyard production (grapes for table, currants, raisins, and wine made) for the seasons 1909-10 to 1913-14 and the percentage of value to total value of all crops, and the average value per acre of vines of bearing age.

| Seasons.                   | Total Value. | Value of Vineyard Production.           |                                               |

#### ORCHARDS.

##### ACREAGE.

The area under fruit culture has been steadily increasing during the last five years. The latest returns show that 24,425 acres are devoted to this purpose. Of this acreage the trees which have reached bearing age account for 17,315 acres; and the trees which have not yet reached bearing age, 7,110 acres.

##### PRODUCTION.

In addition to the fruits mentioned below, considerable quantities of figs, quinces, raspberries, strawberries, and other berry and bush fruits are produced, also almonds, walnuts, and olives.

**Department of Agriculture.      The Recent Appointments.**

**Professor A. J. Perkins, Director of Agriculture.**

**Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S.  
Principal Roseworthy College.**

**Mr. W. J. Spafford,  
Superintendent of Agricultural  
Experimental Work.**

## ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, July 15th. Present—Messrs. G. R. Laffer, M.P., F. Coleman, C. E. Birks, A. M. Dawkins, J. Miller, T. H. Williams (Chief Inspector of Stock), C. J. Valentine, the Director of Agriculture (Professor Perkins), and the Secretary (G. G. Nicholls).

*Election of Officers.*—This being the first meeting of the year, in accordance with the constitution the election of officers took place—Mr. G. R. Laffer, M.P., was re-elected Chairman, and Mr. Fredk. Coleman re-elected Vice-Chairman.

*Planting Reserve, Hundred of Whyte.*—A report was received from the Conservator of Forests to the effect that certain land which the Yongala Vale Branch desired to have planted with trees, was saline and otherwise unsuitable for the purpose. Messrs. Dawkins and Coleman commended the policy of exercising discretion in choosing sites for tree-planting. There were areas near Williamstown which they thought very suitable for timber trees, and upon their suggestion it was decided to ask for a report on the matter from the Conservator of Forests.

*Experimental Farm Wanted in Goode.*—A resolution was received from the Goode Branch of the Bureau—"That the Government be asked to establish an experimental farm in Goode." The Board resolved to send it on to the Minister of Agriculture.

*Smaller Bags of Chaff.*—The Secretary tabled a resolution from the Lyndoch Branch, urging the Board to have the Chaff Act amended so that half-bags (28lbs.) of chaff might be sold. The Branch pointed out that bags of 56lb. weight were inconvenient for travellers and lady owners of cows to handle. Mr. Dawkins said that before making any definite recommendation he would like more evidence that the course indicated was really necessary. He moved that a report be obtained through the Minister from the Chief Inspector under the Act. This was agreed to.

*Along the Murray.*—The Chairman reported on a trip which he had recently made along the River Murray in company with the Director of Irrigation (Mr. McIntosh) and the Secretary of the Board. The party proceeded from Adelaide direct to Renmark. From there they ran out to Ral Ral, about 25 miles distant, and inspected the land proposed to be brought under the extended irrigation scheme. At night a meeting of the local Branch of the Bureau—claimed by the members to be doing good work—was attended, and the following morning the journey was continued to Berri. A meeting

under the auspices of the local Branch was held in the evening, and was attended by about 130 men and some ladies. A great deal of enthusiasm was being displayed in this settlement and the Bureau was attracting much interest and attention. The next day Cobdogla was visited, and in the afternoon there was a capital attendance at a meeting at Kingston. Practically every settler on the area was present, and it unanimously decided to form a Branch of the Bureau. The travellers visited Waikerie that evening at 7 o'clock, and shortly afterward went on to Ramco. In this Branch (known as Waikerie Branch) the membership was limited to 15, consequently several men who would be highly desirable and excellent members were kept outside, with the result that a certain amount of feeling had been developed. The Chairman thought, however, that the visit would have a beneficial effect. The Waikerie people made a request that they should be permitted to have a separate Branch, and when the request came before the Board formally he would have no hesitation in recommending its approval, although the township is only a short distance from Ramco. The settlers were remarkably enthusiastic and progressive.

*A Murray Conference.*—"We suggested that the Branches along the Murray should hold an annual conference," said Mr. Laffer, "as the Renmark people complained that, although they send delegates to the big congress in Adelaide each year, practically the only subjects discussed are sheep and wheat." Continuing, Mr. Laffer said he had been much impressed with the character of the work that was being done on the upper portion of the Murray in connection with irrigation. In his opinion locking the river would be justified if only with the object of facilitating irrigation and ensuring the availability of large supplies of water. The land was magnificent. In a few years Washington navel oranges would be sent away from the settlements, not in thousands of cases, but in hundreds of thousands of cases. There were hundreds of acres, and possibly thousands, carrying orange trees under three years old, and the output of fruit would be enormously increased when they came into full bearing. A tribute to the high estimation in which the land at the settlements was held was the fact that there was scarcely a block now to be had. The manner in which the work of opening up and irrigating this land was being accomplished reflected the greatest credit upon the Director of Irrigation and the officers under him. He was convinced that in the future the irrigation schemes along the river would play a most important part in the development of the State, and that at present the people had no adequate conception of the magnitude of them. In assisting that development the Branches of the Bureau would be a big factor, by, among other things, disseminating the knowledge which the older settlers had acquired through years of practical experience.

*Other Districts.*—Mr. Coleman mentioned that in the previous week he had attended a social gathering in connection with the Strathalbyn Branch of

rendering the texture porous. It is a good plan to spell each yard for a time. During this period it should be growing a crop of some gross-feeding plant, which will exhaust the organic matter in the soil. Rape and all the cabbage kind are gross feeders, and at the same time are excellent green food for poultry.

Where, however, internal parasites (worms, coccidii, &c.) have been prevalent among the birds, the yard should be saturated with a strong solution of one of the many disinfectants available. This should be applied with a watering can furnished with a rose. Allow the disinfectant to soak in for a few hours, then skim the surface soil and remove. Treat the yard again with disinfectant, and next day dig it carefully. Then apply a good dressing of quicklime, which may be raked or hoed in. Let the yard remain for a few weeks and then sow with rape. The soil at the entrance to poultry houses, round the gates, water pots, &c., is generally more saturated with droppings than other parts are. These should receive frequent attention. The houses should be sprayed at regular intervals—say, not less than once a month.

### **Vermin.**

One would think that after the great losses annually experienced by breeders that there would have been a general movement resulting in the extermination in every poultry yard of the tick. Unfortunately, most people in regard to the poultry tick are either lazy, inept, or too ignorant to apply proper methods. Country breeders, many of whom pose as experts, blame the change of water as the cause of death among fowls sent into their particular locality. In ninety-nine cases out of a hundred the poultry tick is the cause. In the north practically every township is a tick-infested area. In the suburbs of Adelaide some localities are free, others are in need of attention, which they will probably receive.

### **Lice, Mites, &c.**

Poultry ticks are known to be carriers of micro-organisms, which ultimately cause blood poisoning and death in fowls. Lice or other mites are also suspected. Where the birds are vermin infested they are not only unthrifty, but the death roll is heavy. In the yards of prominent fanciers I have seen ailing birds, which, on examination, were absolutely swarming with parasites. Provide dust baths and treat the woodwork with kerosene, red oils, and strong disinfectants. A constant watch must be kept so that these pests can be exterminated.

### **Green Food.**

Where possible, sow rape and mustard and plant out silver beet, kail (various), and onions, also garlic bulbs. Green food is of vital importance to poultry. Onion and garlic tops and bulbs are valuable cut up fine for feeding to chickens. Worms cause much mortality among poultry, both old and young. Both onions and garlic contain a principle which acts as a vermicide. Further, the effects of various worm powders are more marked where garlic or onion is fed.

### **Dry Mash for Chickens.**

Make a hopper for dry mash. A kerosene tin will do; cut a slotted hole at the bottom on one side and attach a trough. Fill the tin with the dry mash, which will then gravitate into the trough as the chickens feed. Run a wire lengthwise across the trough to prevent the chickens scattering the mash. The mash may consist of wheat, hulled oats (or groats), skinless barley, maize, and peas. These should be ground as fine as possible. Then add 20 per cent. of charcoal grit and a little meat meal, and a trace of salt. When a month old add 2 per cent. of best bone meal. Meat meal and bone meal as prepared by the Produce Department are both suitable, and are reliable preparations. Chickens will consume a surprising quantity; they drink a lot of water, and they grow and fatten in a most satisfactory manner. Try this method; you will be pleased. Leghorn cockerels fed in the ordinary manner are rarely plump; fed on this dry mash they feed all day, and become very plump. Give them daily two or three lots of fresh, finely chaffed green food. From such a course of feeding you can expect good results—there is variety of food, and you build up a strong bird. The Roberts patent automatic poultry watering apparatus will be installed at Parafield. The cost is not great, and it is certainly a great labor saver. It is easy to keep clean, and as long as there is water in the mains the birds will never run short. Visitors to my office can inspect a model.

### **Work at Parafield Poultry Station.**

So far the hatching season has been satisfactory, and there are about 4,000 chickens doing well. There are hundreds of forward pullets, which will lay about September. The Leghorn cockerels are making excellent growth, fed on dry mash. Egg production is satisfactory, and the percentage of fertility—average of all the breeding pens—is about 85 per cent. The weight of the eggs in the breeding pens of White Leghorns averages 26½ ozs. per dozen.

The weight per dozen ranges from one pen, 24½ ozs., to one with 28½ ozs. The house for the mammoth incubator (a Lanyon machine of over 5,000 egg capacity) is nearly finished, and visitors will shortly be able to see this machine working. Various alterations and additions have been made in the brooder houses. Shortly there will be 26 Cyphers outside brooders spaced about the grounds; and others of various patterns will be fitted up. Additional chicken rearing yards are being erected. A bore has been put down, thus ensuring plenty of water for irrigating green fodder plots. The birds in the various sections of the laying competition are doing well, with here and there a failure. The single testing pens will afford a mass of comparative data of much interest. About September visitors will find much to interest them.

Among various experiments are those dealing with sterilisation of eggs before incubation.

### Points for Consideration.

Every farmer and other producer should own a flock of modern utility fowls, properly housed, and in foxproof yards. The birds should be properly fed, and kept free of vermin.

Suburban residents should erect a small scratching shed to accommodate a dozen layers. From these they will have more than their requirements in eggs, if the strain is right and the birds are properly fed.

White Leghorns of recognised laying strains may be depended upon for profitable egg production.

Where a ~~less~~ number of eggs will satisfy, with the addition of excellent table birds, then ~~there is~~ choice of Wyandottes, Orpingtons, Plymouth Rocks, R. I. Reds, Sussex, Faverolles, and Game.

A small patch of lucerne, well manured, watered, and cultivated will give more cuts and green food of much better quality than a much larger plot which is not properly managed.

Have the nests secluded and dark—hens like to lay in such nests. Moreover, egg eating is less common than where the nests are exposed.

Breed from second season or still older hens, but not from pullets. You cannot expect strong progeny from an immature parent. Use straw freely, it keeps the birds busy scratching and they are warm underfoot. Judging by the wet, muddy poultry yards one often sees it would appear that some people imagine that fowls enjoy these wretched and unhealthy conditions.

Wash all soiled shells of eggs. Dirty shelled eggs, as often sent to market, are a reflection upon the habits of the packer.

Work the incubator according to the instructions sent out by the maker.

Test the thermometer. If incorrect you will have no success in hatching.

If you are experiencing much loss among the chickens when about a week old, try dipping the eggs as follows:—Use either 5 per cent. formalin, pure methylated spirits, or a 5 per cent. solution of any good disinfectant. Immerse the eggs for a minute, and then drain on a wire-netted tray. Place wet in the incubator, and leave for at least 48 hours before turning.

Use moisture in the egg chamber of the machine throughout the hatch. Half the dead-in-the-shell trouble is due to too much heat and lack of moisture. Air the eggs well daily, and increase the length of time as the hatch proceeds.

Do not feed the chickens until they are 30 to 40 hours old.

Ducklings require dry surroundings. The water vessels should always be so protected that they cannot bathe in them, nor make a mess. Feed on bran and pollard mash mixed with plenty of cut green fod and animal food. Keep the ducklings dry; they rarely require artificial warmth. Keep a supply of sharp sand and shell-grit, also charcoal grit. They must have access to drinking water day and night.

A mincing machine costs only a few shillings, but it is very useful. It must be kept clean. Vegetable and house scraps may quickly be minced and fed raw or mixed in the mash.

Keep a close watch upon your birds, and if any abnormal symptoms appear write for advice. Do not wait until the disease has spread and numbers of birds are dying or dead.

All correspondence relating to poultry, the laying competitions, sale of birds and eggs from Parafield, should be addressed—The Poultry Expert, Adelaide.

## PARAFIELD EGG-LAYING COMPETITION.

## REPORT FOR JULY.

*The Weather* has been spring-like with a few very sharp frosts, and generally fine warm days, just sufficient moisture having been experienced to keep the herbage green and succulent. A general rain fell on the 28th with very beneficial results.

*Greenfeed.*—There is abundance of green food, kale, barley, rye, lucerne, and native herbage.

*Broodiness* has, owing no doubt to the warm weather, been prevalent. Fifteen birds in Section IV. have been broody. In Section I., two Black Orpingtons, two White Wyandottes, and one White Leghorn (pen 39) have each had their turn in the broody pen, and have been returned to their laying pens.

*The Health* of the birds has been satisfactory throughout. Among such a large number as are in the competition there is sure to be trouble with some. Two birds in Section I. and two in Section IV. have shown a weakness in the legs, which makes it difficult for the birds to get about. Two in Section I. have had an attack of diarrhoea, and two have shown an attack of "emphysema." All the above have recovered, and have been restored to their respective pens. The following deaths have to be recorded :—One White Leghorn, pen 49, oviduct rupture ; one White Leghorn, pen 8, found dead, no signs to show cause of death ; one White Leghorn, pen 4, cannibalism. Each death occurred in Section I., and replace birds have been received and put in the pens. The general appearance of the birds, with one or two exceptions, is excellent. The pullets in Section I. are as a rule of a good class, and one or two pens are exceptional. Barron's English pens are showing signs of wear and tear, and it is doubtful if they will continue their present score for long. The general purpose breeds in Section IV. are looking very well. All are laying with the exception of the Indian Games, which have just about reached maturity. The White Leghorns in Section III. are doing fairly well. All the single penned birds have become very tame.

*Rainfall.*—The rainfall for the month until the 28th was of a very light nature, as the registrations will show, 2, 7, 13, 26, 6, 2, 2, 2, 62, equal 122 points.

*Visitors.*—Forty-nine visitors inspected the station during the month—total to date 1,225.

## THE WHEAT MARKET.

---

At the present juncture information in regard to the world's wheat crop is of great interest. Under date, London, July 3rd, *Beerbohm's* states—"In the United Kingdom and France the weather has been very fine and favorable for maturing the crops during the past week or so, and there has been a distinct improvement in crop prospects in these countries. With normal weather conditions in the future the yields may not be much smaller, taken as a whole, than last year, with every prospect of the quality being better; much, however, still depends on the weather of the next six weeks. The same remarks apply to Germany, where the yield is not expected to equal last year's big return. In Hungary, according to the preliminary estimate, the yield is about two and a half million quarters smaller than that of 1913, which was also a short crop, and there is every probability that Hungary will have to import about 4,000,000 quarters of wheat during the coming season. In Austria an average yield is expected.

"In Holland and Belgium the crops are making good progress.

"Russian crop advices are not so uniformly favorable as a short time ago, the weather having been too dry in several districts, and it is pretty certain that the official estimate, when received, will be appreciably smaller than last year's. The crops have been ripening satisfactorily and rapidly in the early districts, and harvest is expected to commence in about a week's time; present conditions warrant hopes that the quality will be better than in either of the past two years, although much depends on the weather of the near future.

"The latest advices received by cable regarding the American winter wheat crop point to the yield being about 640,000,000bush., against 523,500,000 bushels last year. The condition of spring wheat, according to Crop-Expert Snow, is 93.2, against 95.5, the official estimate of the condition on the 1st of June. Last year the weather was very unfavorable during June, and the condition of spring wheat deteriorated from 93.5 to 73.8. Present indications are that the total yield of wheat in America this year will exceed 900,000,000bush., or about 140,000,000bush. larger than last year. In Canada present crop prospects are fair and indications are for a moderate crop."

STEAMER FREIGHTS.—(August 1st).—Steamers from South Australia to United Kingdom-Continent, full cargo rates, 17s. 6d. per ton (5½d. per bushel), nominal; to South Africa, 17s. 6d. per ton (5½d. per bushel), nominal. Parcels, Port Adelaide to London-Liverpool, or Continent, 20s. per ton (6½d. per bushel), nominal; Port Adelaide to Melbourne, 12s. per ton (3½d. per bushel); to Sydney, 14s. 6d. per ton (4½d. per bushel).  
 SAUER FREIGHTS.—From South Australia to United Kingdom-Continent, 20s. per ton (6½d. per bushel), nominal; South Africa, 17s. 6d. per ton (5½d. per bushel), nominal.

## DAIRY AND FARM PRODUCE MARKETS.

The Manager of the Government Produce Depot reports on August 1st:—

**BUTTER FACTORY.**—Owing to the very dry spell the quantity of cream to hand was not equal to that of the corresponding month last year. It is, however, gradually increasing, and the quality is excellent. The shortness of supplies is necessarily tending to harden the market, and the present prices are—Superfine, 1s. 4½d.; pure creamery, 1s. 3½d.

A. W. Sandford & Co., Limited, report on August 1st—

**BUTTER.**—Though a steady increase in supplies of both cream and butter has been noticeable throughout the month importations continue to arrive from the neighboring States, and values in butter have only shown slight fluctuations. "Alfa" is selling at 1s. 4½d.; "Primus," 1s. 3½d.; choice separators and dairies, 1s. 1½d. to 1s. 2½d.; store and collectors', 11½d. to 1s.

**EGGS.**—A big recovery in price has been recorded owing to colder weather checking supplies and Western Australia again operating on this market. Hen eggs are selling at 1s. 1d. per dozen; duck, 1s. 2d.

**CHEESE.**—Rates have had to come back owing to the lower figures ruling in other markets. However, this has stimulated local consumption, and the turnover has been extensive, present values being from 7½d. to 7¾d. per pound for large to loaf.

**HONEY.**—As it is late in the season very small lots are offering. Prime clear extracted is speedily placed at 3d. to 3½d. per pound; beeswax, 1s. 3d.

**ALMONDS** also are about finished, only very few parcels coming forward. Brandis are selling at 7½d.; mixed softshells, 6½d.; hardshells, 3½d.; kernels, 1s. 5d. per pound.

**BACON.**—Values throughout the month have been stationary, local forwardings not being quite equal to requirements, and the shortage being made up by importations. Best factory cured sides, 9½d. to 10½d. per pound; hams, 9d. to 11d.; well cut and cured farm middles and hams, 8d. to 9½d.; lard in skins, 8d.; bulk, 7d. per pound.

**LIVE POULTRY.**—The penning during July was very extensive, and attracted a large attendance of the trade. Good clearances were effected with satisfactory prices, especially for quality lots. Good table roosters brought 3s. to 3s. 6d. each; nice conditioned cockerels 2s. to 2s. 9d.; hens 2s. to 2s. 6d. (light sorts selling lower); ducks, 2s. 3d. to 3s.; geese, 4s. 6d. to 5s. 6d.; pigeons, 6½d.; turkeys from 7½d. to 9½d. per pound live weight for fair to prime table birds.

**POTATOES AND ONIONS.**—The potato market has improved considerably, and with many growers in the South-East holding for higher prices, there has been an increased demand for supplies from Victoria. Onions.—Steady quantities have come to hand from Victoria and Mount Gambier, and no alteration in rates has occurred. Present quotations are—Potatoes, £5 to £6 per ton of 2,240lbs. on trucks Mile End or Port Adelaide; 6s. to 7s. per cwt. in the market. Onions, £7 10s. per ton of 2,240lbs. on trucks Mile End or Port Adelaide; 8s. 6d. to 9s. per cwt. in the market.

## RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of July, 1914, also the average precipitation to the end of July, and the average annual rainfall.

| Station.                   | For July, 1914. | To end July, 1914. | Av'ge. to end July. | Av'ge. Annual Rainfall | Station.               | For July, 1914. | To end July, 1914. | Av'ge. to end July. | Av'ge. Annual Rainfall |

\* No report received during the month of July. + Formal report only received.  
† Held over until next month.

[NOTE.—Branches generally are holding their annual meetings during July. In cases where the only business transacted at such meeting has been the reception of the Hon. Secretary's report on the year's work, the meetings have been classed as formal.—Ed.]

## ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

August 12th and September 2nd.

## THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

### REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

#### UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

AMYTON (Average annual rainfall, 11.82in.).

June 8th.—Present: six members and two visitors.

**DAIRYING versus SHEEP.**—This subject was dealt with in a paper by Mr. T. Ward, who expressed the opinion that in this district dairying was more profitable than sheep raising in at least three out of five years. The land was devoid of native bushes and wind swept, and after sheep had trodden down the feed it was blown away. Where big stock were kept this trouble was not so marked. Thirty cows on, say, 1,000 acres, should return £7 or £8 per head, equal to, say, £220 per annum. To this must be added the value of calves and surplus skim milk fed to pigs—the latter would materially enhance the returns. He doubted whether 1,000 acres here would carry 300 ewes with lambs for five months in an average season. From this number, however, he estimated a return of 10s. per head for 200 lambs, *i.e.*, £100; 40 rejects at 7s., £14; and wool from 300 ewes at 4s. 6d., £67 10s.; and 40 lambs, £2 10s.—a grand total of £184. The initial cost of 30 cows and that of 300 sheep would be about equal, *i.e.*, £150. Members agreed that, provided the farmer's family was available for the labor, dairying would be found the more profitable, but otherwise wages would greatly reduce the return.

**PLOUGHS AND PLOUGHING.**—Mr. H. Crisp read a paper on this subject. He favored the five-furrow stump-jump plough cutting 7in. to 7½in. furrows for this district; the lighter it was the better, due regard being given strength and durability. One-piece bodies were less likely to become fouled with rubbish. The narrow-furrowed plough cut the ground better, and was much more satisfactory in shallow ploughing. Where there was no danger of turning up the clay subsoil, ploughing in this district should be to a depth of 3½in. The sod should be turned properly by the mouldboard. A team of eight horses should be worked with leaders. Members favored the narrow furrow of from 7in. to 8in. The Hon. Secretary (Mr. S. Thomas) thought the curve of the mouldboard of more importance than its length in securing lightness of draught and a well turned sod.

ARDEN VALE AND WYACCA (Average annual rainfall, 16.65in.).

July 6th.—Present: five members and three visitors.

**FENCING.**—Mr. O. E. Hannemann read a paper. At such times as these, he said, when the weather conditions made it impossible to get on with the seeding operations, attention should be turned to such matters as repairing fences. Handy and serviceable gates should be erected. Members agreed that the useful life of fences was greatly increased by attention to necessary repairs.

MORCHARD (Average annual rainfall, 11in. to 12in.).

May 2nd.—Present: seven members.

**SEEDING.**—The hon. secretary (Mr. B. S. McCallum) read a paper. He had had very good results from dry sown crops when the land was free of weeds. If dry sown land were twice harrowed after a good rain considerable benefit would result, especially in

sandy or light soil that did not set hard. He preferred this to sowing immediately after a good rain and not waiting for the weeds to grow. When the farmer was able to get his seeding over in a few weeks on account of having plenty of feed and horses in good condition, he advised waiting for rain to cause the growth of rubbish; but when feed was scarce and horses in low condition it was unwise to leave a large area to be sown after rain. If the early sown crop became "dirty" the worst patches could be cut for hay. Mr. W. Reichstein agreed; he thought it wise to put a portion of the land in dry, seeing that the season was so late in opening. Land which he had rolled last year had yielded more than that not so treated. Mr. H. Kupke favored late sowing. Harrowing dry sown land after a good rain was advised. Mr. E. J. Kitto had drilled manure on to fallow early, when the land was dry, and broadcast the wheat and harrowed it after rain with the result that a good crop was secured. Messrs. R. Jasper and R. Kitto agreed with the remarks of the writer of the paper.

#### MOUNT REMARKABLE (Average annual rainfall, 14-43in.)

Present: fourteen members.

**STAR THISTLES.**—The President (Mr. N. S. Giles, B.Sc.) read a paper as follows:—  
"The noxious weed which is generally known as the star thistle is wrongly so called. The true star thistle is much more bushy in its habit of growth than this one, and has a flower similar in color to that of the Scotch thistle. Although by no means a desirable plant to have about one's property, it does not appear nearly so difficult to keep in check as the yellow-flowered abomination with which agriculturists in South Australia are only too familiar, and which is the saffron thistle. It is so universally known as the star thistle that these notes will from this out speak of it by that name. It appears to thrive with equal vigor both under the moist conditions of the South-East and in the dry areas of the North. It has lately become a prominent feature in the park lands of Adelaide, and if left unchecked will, in all probability, soon spread over the whole State. Since the advent of the harvester the seed may very easily be introduced to new areas through the medium of wheat, oats, or other grain. Farmers who are the fortunate possessors of clean land would therefore do well to exercise great care in this respect when obtaining a change of seed. No source of supply should be considered above suspicion, the only safe method being to make a close examination of a fairly large sample of the grain. Even if this is satisfactory it is safer not to obtain seed from properties which are badly infested with star thistle. The weed is so detrimental both in grazing and cultivated land, that wherever possible it should be destroyed. This however, is unfortunately by no means an easy task, and where the star thistles have obtained a good hold their complete removal must prove a long and expensive business. On arable land much can be done by judicious cultivation, but on the rougher grazing country, where star thistles have become firmly established, the problem becomes a serious one. If undertaken in a systematic manner, however, there is no reason why the weeds may not in time be eradicated. One of the worst difficulties is the hardness of the seed, which enables it to remain in the ground for a number of years without injury. As the result of observation the writer believes that the seed very rarely germinates until it has been buried for at least a year, and it has been conclusively proved that, even when not buried by cultivation, it may remain dormant for at least four or five years. For the past five years a paddock which was formerly badly affected has been kept under careful observation. The thistles were hoed up every year, and great care was taken that none were allowed to go to seed, yet the supply is even not now exhausted. Some seasons seem to be much more favorable for germination than others, the present one promising to be good in this respect. It is probable that burning would hasten the germination by softening and cracking the hard casing of the seed in the same way as with the wattle. If it is desired to get rid of the star thistle care should be taken that no plants are allowed to go to seed. In cases where the area affected is too large to be thoroughly dealt with in one season, it is better to concentrate attention on one portion of the area and get it properly cleared rather than make a poor job of the lot, for, although the thistles may be kept in check, they will need attention year after year. The writer has found that the best results are obtained by hoeing the thistles just before flowering commences, the plants being cut below the surface of the ground. If the hoeing is done too early, or the cut is not deep enough, the plant will send out shoots and will probably bear more seed than if it had been let alone. If the plants are allowed to start flowering before hoeing, the seed will mature just the same, unless the flowers be cut off the stem. The cutting in fact, then, facilitates the spread of the thistle, as the loose plants are blown about by the wind shedding seeds as they go. Under natural conditions the seed does

### MIDDLE-NORTH DISTRICT. (PETERSBURG TO FARRELL'S FLAT.)

BEAUFORT (Average annual rainfall, —in.).

July 2nd.—Present: eight members and five visitors.

**HORSES.**—Dealing with the subject of farm horses, in a paper, Mr. C. W. G. Underwood expressed the view that horses for farm work should be as strong as possible, with flat bone and plenty of hair, which he considered an indication of strength. Slow, sluggish animals were to be avoided, and the team should be able to walk and trot well. In addition to draughts, it was advisable for the farmer to have two or three medium draughts out of a pony mare by a draught horse. All should be mares, with the exception of two or three geldings for shaft work. Only dry mares should be put to the horse; a better foal was the result. Breaking could be commenced when the animals were two years old, light work only being given. This helped to develop bone and muscle. Handling foals tended to make them cunning. A good yard with a stall to catch the animal was necessary in breaking. The beast should be lassoed, and a turn or two taken round a strong post. Choking down was to be avoided if possible. The operator should work his way along the rope, until he was able to rub the horse's head; rubbing the eye, he said, soothed the most vicious beast in a short time. When the winkers were on, the rope should be taken off the neck and attached to the bit. The first lesson should be leading; the wagon saddle and breeching should then be put on, and the chains tied underneath. The animal could then be tied up, and the next day put in a light trolley with a good brake. If leather traces were used the beast was less likely to kick. The Chairman (Mr. W. W. Mugford) thought a good strong draught horse the best all-round animal for farm work; it was also of more commercial value. He could not see that there was anything against breeding foals from mares every year, though he thought it was more difficult to get a wet mare in foal. It was a good thing to handle the foal a little, at least to tie it up, in order that it might become used to this. Mr. J. Sampson did not think the heavy draught horse the most suitable for farm use. He recommended a good strong clean-legged animal. The draught horse, as a rule, was too slow. He thought a crush pen better than a lasso for catching a young horse; it did not knock it about so much. Young horses required more handling than they usually got before breaking in. It was good to work horses at two years, so long as the work was light. It was no harder to get a wet mare in foal than a dry one if she was in good condition. Mr. J. Dohse recommended a good heavy draught horse for the farm, the more weight the better. One visitor favored a good strong clean-legged horse, the Suffolk Punch was good. He thought a mare could have a foal every year without harm, as long as the foal was weaned early. Mr. P. H. H. Underwood considered a good medium draught quite as good as a heavier draught. It was usually more active, and could be used in the trolley. It was advisable to breed as many foals as possible. The mares needed careful attention, and should not be worked too hard. Weaning foals early was likely to stunt the animal and make it small and weedy. The crush pen was much better to catch horses than the lasso. Those horses he had worked when young were much bigger and better than those not given work.

GEORGETOWN (Average annual rainfall, 18.32in.).

June 13th.—Present: seven members.

**PREPARATIONS FOR SEEDING.**—Mr. J. Higgins read a paper in which he said fallowing should be done early, the ground being ploughed to a depth of 4in. It should then be harrowed, and, during spring, cultivated to destroy weeds. The cultivators should also be used after rain in summer. The seed wheat should be carefully cleaned and pickled a week before seeding, 1lb. of bluestone being used to every four bags. Seventy pounds of seed per acre should be drilled in to a depth of about 2in. and cross harrowed. Late varieties, such as Marshall's No. 3, Federation, and Yandilla King should be sown first. About 30 acres of an early wheat, such as Gluyas or Golden Drop, should be put in to enable an early start to be made with haycutting. Paddocks dirty with wild oats should be sown with early wheats; and if the oats were very troublesome, it was advisable to cut the crop for hay before they seeded. Mr. Geo. Hill did not approve of working fallow after summer rain. Mr. J. McAuley thought summer fallow would be a failure, especially after a dry winter.

LEIGHTON (Average annual rainfall, 16in. to 17in.).

July 4th.—Present: 20 members and seven visitors.

**FARM MACHINERY AND IMPLEMENTS.**—Mr. W. G. Bailey read a paper on this subject. Expensive implements and machinery were necessary in farming at present, he said,

and every care should be given these. Drills, wagons, harvesters, binders, &c., should be protected by a substantial shed, drills being taken to pieces and cleaned before being put away. Bolts should be kept well screwed up. The earth should be scraped off the mouldboards of ploughs and a good coating of grease applied. Harrows should be placed on end when not being used. The log of the roller should, when not in use, be kept from contact with the earth, and the framework given a coat of paint.

#### MOUNT BRYAN (Average annual rainfall, 15·8in.)

July 4th.—Present: 12 members.

**FALLOWING.**—In a paper on this subject the Hon. Secretary (Mr. H. L. Hatherly) said—"It is not an easy matter to lay down any hard and fast rules as to just how the land is to be worked, as a treatment that would be proper and advisable in some paddocks might not be so in others. Much must be left to the farmer's judgment as to what implement he should use. There are, however, some principles for guidance. One should, in all cases, fallow as early as possible, as there is a better chance of doing the work while the ground is in a moist condition. The land not only works better, but being ploughed early will get a larger proportion of the winter rains into it. Another important consideration is that the moisture is thus more readily absorbed, sinks deeper into, and increases the fertility of the soil. Early working will encourage the germination of any seeds of weeds or rubbish that may remain in the soil, and these may be destroyed by a later cultivation or fed off with sheep. However, whether sheep are kept or not, I would harrow and cultivate all the heavier lands, as apart from the destruction of weeds, such cultivation is of direct benefit to the soil. Always aim at doing the work while the ground is damp. The depth to which it is to be ploughed must be left to the discretion of the farmer, and should be regulated according to the nature of the land being operated on. Nevertheless, I advise ploughing in our district to a depth of from 4½ in. to 5 in." In the discussion that followed the depth of ploughing was discussed. Messrs. Jefferies and Phillips thought 4½ in. or 5 in. too deep, but the majority of members agreed that where the subsoil was deep, as in this district, good results were obtained with ploughing to a depth of 6 in.

#### MOUNT BRYAN EAST (Average annual rainfall, 16in.)

July 4th.—Present: seven members and one visitor.

**BREEDING, HANDLING, AND SELLING SHEEP.**—Mr. R. Thomas read a paper on this subject. He said, "If the country is sandy and liable to drift one should be very careful not to overstock it. In windy weather the feed will be cut up with the sand, and the result is that the land is spoilt for a considerable time. On the other hand if the country is understocked the grass will spread over the bare patches and stock will always be in good condition. Saltbush and scrub must also be understocked or the results may be as bad as in the sandy country. The arrangements of paddocks and dams is also an important item. Paddocks should be shapely, and should contain as great a variety of feeding as possible. Where they are not too large it is better to have one good dam watering the two paddocks than have two indifferent dams, but where the paddocks are large they should have a good dam centrally situated. One may have a large dam alongside a division fence and a smaller one in the centre of the paddock and close off the good holding dam when there is water in the other. If sheep are travelling to water in one corner they will cut up the land near the dam, as they always come to water the same way and eat off all the feed on that corner while the far corner is hardly touched. A useful class of fence for subdivision can be made from large posts half a chain apart, with droppers every 10ft. or 11ft. There should be five wires, which need not be thick but of good quality. If any cattle are kept a barbed wire should be placed on top. The fence should be about 3ft. 3in. in height, the gates being in places where sheep can be easily driven through from both sides. The gates should open both ways and right back to the fence, so that no sheep or lambs can get behind them. Where the feed and climate are suitable market lambs are preferable, as practically only two-thirds of the stock need be kept for the same return, and when the number is greatest the feed is best. The class of sheep is very important. After a number of years experience I find the Lincoln-Merino and Leicester-Merino cross ewes give the best result. If the country does not lend itself or the seasons are not reliable enough for lamb-raising, wool should be the objective. Whichever class one is going for the best procurable will pay best in the end. For wool the sheep should be of robust constitution, carrying clean wool of long staple about 64's quality. The shearing-shed should be in a convenient place on the run and a little bigger than necessary, as this will give plenty of room for working

the wool, and the sheep will not be overcrowded at night. When one has more sheep than the usual complement the shed will then not prove inadequate. There should be plenty of room under the grating, as this provides good ventilation for the sheep, and gives them a chance to cool off after being penned. It also makes it easy to clean, which should be done every year after shearing. The wool should be handled carefully as it is easily made dull and dirty. First take the fleece from the board without tangling it and throw it over the table with the crutch towards the operator and the outside surface upwards. Skirt by taking off the short edges, stains, and sticks from the neck. Then fold and roll from the tail keeping the shoulder wool on the outside. This shows the fleece to the best advantage. The bales should be packed evenly, and be of about the same weight for the same class of wool. In branding the bale care should be taken. If a person is not handy at cutting stencil plates he should pay to have them done by a tinsmith. A few shillings spent this way will bring in a good return for the outlay. Adjoining the shed should be a good set of sheep yards. Care should be taken in getting these laid out nicely. The shape makes a lot of difference in the way the sheep go through. A good drafting arrangement is necessary. The crush pen should be made without more corners than is necessary. The race should be made running east and west, with a light swinging gate and two good sorting pens. These three pens are where the work is done, and so should be erected strongly with good swinging gates and convenient latches or hooks. At intervals of a few years the land requires a complete rest from sheep-grazing. A year's rest puts new life into the land. It also gives the seed a chance to recover. One can either sell out most of the sheep or systemically rest the paddocks in turn, whichever suits the conditions. In shifting sheep from one paddock to another do not wait too long, or both land and sheep are affected detrimentally. Always keep a sharp eye on pests and noxious weeds. These, if taken in hand at once, are generally easily destroyed, but if neglected prove serious to the landholder."

June 8th.—Present : 10 members.

**FARM BOOK KEEPING.**—The following paper was read by Mr. F. C. Catt :—"A farmer's books should contain a complete record of every division of the farm accounts. While they should be simple and easily understood, yet, if properly arranged and carefully kept, they should show, without much trouble, whether the farm is being run at a profit or a loss, and which departments are yielding the best return for the time and money spent, besides affording valuable comparisons year by year. In order to accurately determine this it is necessary to open up accounts representing various classes of expenditure and income, debiting each account with the amount spent, and crediting it with the value of the produce. Take, for instance, the crop. To ascertain the net profit derived from this source, the crop account should be debited with all money spent on it from the time the ground is fallowed to the point when the hay or grain is marketed (including cost of fallowing, artificial manures, seed (whether purchased or home grown), plough shares, hay and chaff used, binder twine, cornsacks, wheat carting (if paid for), and depreciation of implements), and credited with the sales and stock on hand at the end of the year. The balance will be the profit. The other principal accounts necessary on the average farm would be—(1) *Livestock*, which should be debited at the beginning of the year with stock on hand and all purchases as made, and receive credit for all sales and the stock on hand at end of year; the balance representing the profit or loss for the year. Where there is a considerable amount of dealing in various lines of livestock this account may be subdivided into separate accounts for horses, cattle, sheep, &c. (2) *Working Plant*.—Debit this with the value of the plant at the start of the year and with all purchases. At the close of the year make a valuation of the plant and credit this, the difference will be depreciation, which, as previously stated, should be charged against the crop. (3) *Permanent Improvements*.—For all houses, sheds and stables, fencing, dams, &c. (4) *Land Purchase Account*.—Credit this account with the purchase price and debit it with amounts as paid off the principal (not interest), and so on, with such accounts as hides and skins, wool, dairy produce, property, &c. Against the farm expenses account I would charge only such items as repairs, rates and taxes, insurance, interest, and rent. Moneys drawn by the farmer for his own personal use might be debited to a private account. At the end of the year the profits or losses in the various accounts should be transferred to a profit and loss account which will show the net result of the year's transactions, while a balance-sheet showing the assets and liabilities of the farm can be compiled from the accounts which remain open. Each transaction should be entered as it occurs, otherwise items become overlooked and the value of the work is discounted."

**SHEEP MAGGOT FLY.**—Mr. A. L. Steele read a paper, as follows:—"This pest so far has not worried sheep owners in South Australia to any very great extent, but to gauge the damage done by this fly and its kindred species I can quote New South Wales, the authorities in that State estimating the loss of sheep due to flyblown alone at one million a year out of a total of about 49 million sheep. First of all, I shall give a brief outline of the flies that cause these enormous losses, there being several different species, but before going further I might say that portion of my notes have been obtained from a treatise issued by Messrs. Cooper & Nephews, and containing an essay by W. W. Froggart, the New South Wales Government Entomologist. The bright metallic green fly (*Lucilia sericata*) that does the damage to sheep and wool in England is not one of the culprits here in Australia, and although it has a wide range over this continent it has not yet been bred from blown wool; apparently it is contented to confine itself to offal. The bronzy green maggot fly (*Lucilia caesar*) is also one of England's sheep flies, but, like the former, only worries the householder in Australia. Our enemies are (1) the mottled blowfly (*Calliphora oceanica*), (2) the large yellow blowfly (*Calliphora villosa*), (3) the metallic blue blowfly (*Calliphora rufifacies*) and all are indigenous to Australia. Nos. (1) and (2) are very common all over Australia, and are of similar habits, both blowing wool, and also meat in a house. These are the parents of the common smooth-bodied maggots. No. (3) also has a wide range over Australia, and is the parent of the hairy maggot, but it very seldom comes into a house. To show the enormous rapidity these flies have in breeding, Mr. Froggart, from a pound of blown wool, obtained 1,050 blowflies, and allowing that half of these were females, and all lived to deposit one batch of eggs, we would have in three generations 16½ million flies in about eight weeks in mid-summer. In early summer they deposit eggs or larvae, but in mid-summer the eggs hatch in the female's body, so instead of eggs she deposits living maggots which immediately begin to crawl. The number of eggs obtained from a female's body after dissection varied from 50 to nearly 200. The maggot, after it is born, takes about six days to become full grown. After that it goes into its second stage as pupa, that is chrysalis, and as such remains for about 14 days, from which it then emerges as a perfect fly. One experiment showed that eggs laid on the 4th of December produced, after going through the maggot and pupa stages, perfect flies on the 22nd—18 days. A specimen of the large yellow blowfly taken in a house and placed upon some meat laid 180 eggs, all of which were crawling maggots next morning. It has been proved by scientists that blowing wool on a living sheep is an acquired habit of the fly, as it is only of comparatively recent years that sheep have been attacked. Many reasons are put forth to account for this new habit, amongst them being the extra density of wool, and with it in good seasons, condition or yolk, which is in other words fat, and therefore attractive to the blowfly; the wholesale destruction of rabbits, and consequent breeding of maggots. How this curse is to be put down is occupying the attention of all sheepowners in Australia. Many different methods of combating the nuisance have been put forward, amongst them being to leave about 3in. or 4in. of tail, and so enable a ewe to keep her tail continually moving and prevent the fly settling upon the stained wool. But against this the long tail can easily cause the ewe to become daggly if she happens to scour, and so become a tenfold easier prey to the fly. Another method, and one which is by far the most popular, is to crutch the ewe prior to lambing, as near as possible to the time as is safe to handle her, say about three or four weeks. This will prevent the afterbirth and blood adhering to the wool. In opposition to this I might say that it is only in odd years in our back pastoral country that the flies are bad, and then only after a good winter rain, and it seems almost unnecessary that the stations in the so-called dry country should crutch when it is only one year in three or four that the sheep are attacked. But in this district, where we have an assured rainfall, it is my belief that crutching is the best method. Means of preventing the breeding of the flies are the removal of all refuse and carcasses and destroying possible breeding places by burning thoroughly. When dressing blown sheep to prevent the maggots from becoming flies it is advisable to throw into a bag or tin all blown wool taken off the sheep, and if only a small quantity to burn it. But if a number of sheep are treated dip the wool in a chemical solution, such as Cooper's dip, carbolic wash, or kerosine. Also it would be a good plan to do all sheep on a bag or sheet and all maggots left on the sheet should be destroyed. The maggoty sheep can easily be detected, even when first attacked, by restlessness, vigorous wagging of the tail, biting the tail or flank or wherever the affected part is, stamping its feet and running forward with nose on the ground. In the later stages the wool of the affected part becomes very dark, and is noticeable a great way off. The sheep is very listless and, if not attended to, soon dies. So far no solution has been discovered which will effectively deal with the fly for any period. Many preparations,

and all the well-known sheep dips will kill the maggots, but in a few days the old places are re-infested. I, myself, have used several dips—tobacco juice, kerosine, turpentine, etc., with fair success, but often the patients had to be dressed again. When first applied all of these are very severe on the maggots, which come swarming out in thousands, and in a few minutes die, but apparently the smells of the liquids are not lasting enough. What is required is a solution that will either prevent the fly depositing its eggs on the wool, or kill the young maggots as soon as they are hatched, and at the same time not destroy the wool. Bluestone in a 5 per cent. solution has been found very effective in destroying the maggots, but it is very injurious to the wool. The stock branch of the New South Wales Government, in experimenting with a 1 per cent. solution, found that the bluestone permanently dyed the wool; therefore this treatment cannot be advised, but should it be used care must be taken only to spray the already urine-stained wool. As in most cases 'prevention is better than cure,' and with that in view, crutching the ewes just before lambing, and weaners in April seems most advisable. This is now being carried out on nearly all the stations in the grass country of Queensland and New South Wales, and one can realise it is no light task when on many of the runs 100,000 breeding ewes, besides the ewe weaners, have to be put through. Some stations go as far as to take off all stained wool from all sheep, as even wethers are in some localities being blown about the pizzles. My experience in South Australia has been that in a good season, which means ideal conditions for the fly, *i.e.*, dampness and warmth, early shearing is an important factor; so preventing the flies getting on to the long stained wool at the breech. No rules can be laid down as to treatment, for, as I mentioned before, no reliable solution has been discovered, but Stockholm tar, kerosine, turpentine, bluestone, and the well-known sheep dips, such as Cooper's, Little's or Quibel's are all good for the time being, and should be successful if the treated sheep can be watched and re-treated in a few days."

#### REDHILL (Average annual rainfall, 16.79in.).

July 14th.—Present: 17 members and two visitors.

**PIG RAISING.**—Mr. F. H. Wheaton read the following paper:—"In introducing this subject the fact places itself before all of us that, under ordinary circumstances, *i.e.*, conditions which have normally existed during the last 12 years, facilities in this district do not offer such advantages for raising pigs as may be the case in other localities. I shall consider the position as if markets were in close proximity. Whatever breed of pig one may approve and rear matters not, so long as the maximum profit is being secured. Some breeds mature quickly, others are slower; some are reared for the hams, others for bacon, and so on, always being ruled by the market. The breed mostly seen in Australia is the Berkshire, although several others are becoming more evident. The Berkshire is, perhaps, the most popular, because of its general hardiness. It can stand the hot sun better than most breeds, is thrifty, fattens readily, and the flesh is of good quality with fair distribution of fat and lean. It matures early, and kills well at any age. However, the best breed is a matter of opinion, and I shall not dwell on that point. *General Management.*—There is no farm animal that eats more in proportion to its weight, or turns its food into a saleable carcass so rapidly or efficiently as the pig. Under natural conditions, the pig is a grazer. Better pork is obtained from the animal which is run in a small paddock, and sty fed at the last, than one which is sty fed throughout. Sties should be airy; but not draughty. They should be in such a position as to be open to the sun. The initial outlay for good sties is perhaps rather heavy, but subsequent profit in the way of healthier and better pigs will amply repay. Sties should be in a well drained position, and attention should be fairly often and regular. Bedding is necessary when the weather is cold, especially for sows. It is a good plan to put a small quantity of ashes into the sty occasionally; this conforming somewhat to the natural taste of the pig. *Feeding.*—This will vary somewhat according to the age and state of the pig. Milk forms a valuable ingredient of the animal's ration. All grain should be soaked; which has been proved to be better than boiling. Young animals should be generously supplied with pollard and barley meal, the meat ration being increased with the pig's age. Allow plenty of exercise to ensure the development of strong sound limbs, and to prevent over fattening. When possible, some form of greenstuff, cabbage, &c., should be given; refuse from the kitchen is valuable. When a sow is pregnant, the food should be increased in richness, but the quantity should not be sufficient to produce fat. The food for a hog will differ somewhat from that of young pigs or sows. When not working, a boar will thrive almost entirely on greenstuff; but as work increases the ratio of meal should increase. Pigs at all ages should have access to plenty of water, troughs being kept clean by daily washing. *Selection of Breeding Stock.*—Too much attention cannot be given this, as a false move in the selection of the boar especially will affect a great number in a short time. The following general

rules will perhaps be acceptable:—(1) Select from reputed and long-established breeds; (2) do not consider show success first; (3) pure-bred pigs should be chosen; (4) inspect if possible, the animal's immediate ancestors; (5) see that the sexual organs of the boar are well developed, and that the eye is bright and lively. A breeding animal should be one of a large litter, not too big, nor yet too small; big boars are generally slow and do not last long. The selection of the sow is perhaps more important than the boar, as it is generally believed that the sow influences the internal organs; hence the aptitude to grow and fatten at a profit. See that the sow's teats are well developed; there should be 12 or more. Avoid thick, short necky, heavy shouldered sows, as they are generally poor mothers and slow breeders. A boar should be first used when about eight months old, or older, depending on the breed. Increase the number of sows as the boar grows older; but it should not be overworked when young. When a number of sows are to be covered it is better to keep the boar penned up, and put in the sow only for service, thus conserving the vigor of the boar. An alternative is to allow the boar to run with the sows, and if inclined to overwork pen it for a time. From 50 to 60 sows is a fair season's work for a boar. The sow should be put with the boar when nine or 12 months old. A sow's first litter is as good as any subsequent offspring. If the condition of a sow falls she should be spelled for a while. Some sows, if not put to the boar for some months, may get shy, and refuse to be served. This shyness is often worked off by feeding albumenoids, such as peas, beans, &c. If, however, the sow is obstinate, let her be served in quick succession by two or three boars, towards the end of the heat. The period of a sow's gestation is three months three weeks three days, or 16 weeks. The sow's sty should be roomy, not less than 10ft. square. Plenty of short bedding should be allowed; if straw be long young pigs are apt to get lost and injured. *Parturition.*—The sow generally farrows without any serious after effects; but, if exhausted, a little stimulant, such as a teaspoonful of gin, will often help. The food for a short time before and after pigging should be soft and sloppy, changing after parturition to meal or pollard with milk. Two ounces of sulphur and a little nitre will help the sow if she is at all constipated. Her sty should be cleaned out, but the nest left undisturbed. A little exercise every day will do much good. Feed the young pigs on milk, if possible; if not, pollard gruel is good. Generous feeding is required, or else all suffer, and the sow may refuse the boar afterwards. The time for weaning will vary a little, according to circumstances; but from eight to nine weeks will generally be found most satisfactory. A sow comes in season about four or five days after the pigs are weaned, 10 to 14 days after that, and then every two or three weeks regularly. Under ordinary conditions, a sow will rear two litters a year, five litters in two years is too much. Young boars can be castrated when four or five weeks old or when weaned. For fattening young pigs the best feeds are soaked grain. Barley makes the best quality pork, but peas cannot be beaten for giving a sweet flavor and firm consistency to the meat. Wheat is considered to be better than other cereals, but is generally too dear when compared with barley or rye, when obtainable. Feed the young pigs at short intervals; they eat more, fatten more quickly, and do not waste so much as if fed at long intervals and given bigger feeds. A fat pig will dress up to 90 per cent. of good meat. It might be well to mention here that pigs are subject to rheumatism. This is often due to over-feeding, or the food may be too rich. Dampness, draught, or insufficient bedding may result in this ailment. A change of food will help in preventing this trouble. A little vegetable will also act to the advantage of the pigs." Mr. Stone thought wheat too expensive to feed to pigs. However, this grain, with milk, yielded a firm and sweet bacon. Mr. Pengilly had found the Berkshire-Essex cross very profitable.

SPALDING (Average annual rainfall, 20.25in.).

June 6th.—Present: 12 members and 2 visitors.

**FARM HORSES.**—In a paper dealing with the care of farm horses, Mr. J. H. Pluckrose said he preferred a stable with stone walls and straw roof, facing the east, and built on rising ground with a gentle slope. A stack of straw should be placed in the paddock to provide shelter. The animals, if allowed freedom in the yard were less likely to be injured than when tied up. They should be groomed, or at least have their shoulders cleaned, every morning. Feed should be given them three times a day, and they should have access to water before feeding. Hay chaff with bran and oats with soaked barley, and one packet of Epsom salts once or twice weekly, would be found a good system of feeding. Rock salt should always be available in the mangers, and well water would be found better than dam water for drinking purposes. Mares shortly to foal should be kept apart from other horses in a small paddock close to the homestead. They could be worked with safety up till within a few days of foaling. Two or three foals should be bred each year to keep up the strength of the team. The best sire procurable should be used.

Horses broken at 2½ years could be given light work through seeding and would be available for fallowing. For farmwork he favored the short nuggetty animal. Mr. Thorn advised damping the chaff before feeding. Rolled oats damped 24 hours before being put through the crusher would be found better than crushed oats. King's Red and King's Early were the best hay wheats, both from the standpoint of feeding value and palatability. Members generally favored rolling or bruising oats in preference to crushing or grinding. Sore shoulders were generally caused through the team being overtaxed.

#### WHYTE-YARCOWIE (Average annual rainfall, 13.91.n.)

June 8th.—Present: 12 members and one visitor.

**WHEAT IMPROVEMENT.**—The Hon. Secretary read from the May number of the *Journal*, pages 1061 to 1064, the report of an address by Mr. F. Coleman on "Improvement of Wheat by Grading, Selection, and Cross Fertilising." In the discussion, Mr. Lock said in his opinion one could not expect much improvement from grading alone, apart from the obvious saving for a better use, of the broken grain and rubbish; but he thought there were great possibilities in selection if carefully carried out. As far as cross fertilisation was concerned this was a matter for experts. The average farmer could not devote the time, nor had he the knowledge or patience required to attain success in such work. Mr. Wittwer did not agree with Mr. Lock in regard to grading. He had tried it, and was sure his crop had benefited to the extent of 2bush. per acre, besides leaving the inferior grain for fodder. He would like to see the matter thoroughly tested on lines somewhat as follows:—Take a certain variety of wheat and grade it out in three standards—1st, 2nd, and 3rd quality: these to be sown side by side and harvested separately, the test being carried on over a period of three years. In this way a satisfactory decision could be arrived at. The Chairman (Mr. G. F. Jenkins) was quite satisfied that much good would result from both grading and selection of seed. Mr. McGregor had tried a small experiment on the lines suggested by Mr. Wittwer, and thought he could see a difference in favor of the first grade; but not having harvested the plots separately the result was indecisive.

#### YONGALA VALE (Average annual rainfall, 13in. to 14in.).

July 4th.—Present: eight members and six visitors.

**FARM MANAGEMENT.**—Mr. W. Edson read a paper. The land should be worked with a skim plough as soon as possible after harvest, he said. Stubble should be burnt early in order to destroy weed seeds. Fallowing should be commenced early in June and completed by the end of August. It was a good plan to devote one day each week to harrowing; the ground would be found to work down better if not left too long. Early fallowing ensured early germination of weeds, thus enabling the cultivating to be commenced early in spring. Harrowing during the summer kept the surface loose and tended to conserve moisture. **Horses.**—Horses should be well brushed daily; combing was liable to cause sores on account of scratching. Regular feeding in small quantities should be practised. Oats should be given with the morning and evening meals and bran with the midday feed when the animals were working. Once or twice a year the horses should be kept without feed for 12 hours and then drenched; this prevented trouble with worms. **Implements.**—A shed for implements should be constructed of stone and iron, away from the other sheds, which might be roofed with straw. Machinery should be housed immediately it was finished with, binders and harvesters being thoroughly cleaned before being put away. Mr. Miller advised ploughing in straw in preference to burning. He quoted instances where he had obtained 8bush. to the acre more where the former method was adopted in preference to the latter. Members generally favored the use of the skim plough for fallowing, as it packed the land closer than other implements.

### LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

#### CLARE.

June 5th.—Present: 20 members.

**SMUT.**—Mr. Rowland Hill read a paper on this subject. The smuts, he said, constituted a family of parasitic fungi which very materially affected the yields of cereal crops in this State. Dealing with the spores of the smut he said—"They germinate by contact with moisture added to the soil by the autumn rains. A long tube is emitted, through which

all the living matter is concentrated near or on the surface of the ground. If this tube meets a young wheat plant it has the means of penetrating the stem of the wheat at the collar where the roots start from the stem, but it is only very young plants that can become affected with the disease. When it has penetrated the young plant it subdivides into a series of mycelium threads in the tissues of the plant, and the smut lives on the sap from the cells of the wheat plant, so that actually the parasite grows up with the plant, and at this stage it does no harm, but on the contrary the plants affected have a much healthier appearance. As the mycelium grows up with the plant the portions below die, so that if a crop affected is cut, say, when just coming into ear the second growth will not show any signs of the disease. As the crop ripens the mycelium threads concentrate in special portions of the plant. In the case of loose smut, it is the ears of the wheat, and on them are formed large masses of black spores which fill up the ears, destroying the grain altogether. There is no doubt that the loose smut of wheat is conveyed to the crop almost entirely from the ground. The same may be said of flag smut; oat and barley smuts arise both from soil and contamination of the seed. Bunt arises almost entirely from seed contamination. The most obvious means of destroying the spores in the ground is a change of crop, and this is all the more easy in that the various cereals are affected by different parasites, but when bare fallow always precedes a cereal a change is not absolutely necessary. Where the fallow has been worked suitably and weeds cannot make any growth thereon, this land should be free from infection when put again under the same type of cereal. The use of manure that is not well rotted should be avoided, because it is not only liable to carry the spores to the ground, but it acts as a medium in which the parasites are able to live temporarily. Wheat bunt differs from the loose smut in that it develops in the grain itself, and therefore is later than loose smut. It does not burst until threshing, so that the whole of the harvest may be more or less affected by a few bunted heads bursting and the spores adhering to the grain. Affected plants are always of a darker green, both in flag and head. Later on the bunted head stands erect when others, non-affected, droop a little. This fungus is different from loose smut in that the spores are actually on the wheat grain itself; when they germinate they immediately attack the plant with which they are in contact." In answer to a question as to the best method of pickling wheat with bluestone, Mr. Hill said it was advisable to pickle on a good floor, provided the grain was shovelled well, an opinion that Mr. Birks entirely agreed with. Mr. Hill also stated that a quantity of grain was not touched at all with the bluestone when pickled in a bag. If the crop were cut for hay before the grains which were affected were in the powdery stage, or if they did not turn into the powdery stage during the period of drying, there would be no risk of contaminating the soil with smut. Several members preferred pickling their wheat in the bags. The strength of solution used was 1lb. bluestone to 10galls. of water, which was sufficient to pickle 8bush. of wheat thoroughly. Mr. Jarman had devised an economic method of dipping wheat, whereby all grains were covered by the pickling solution. It consisted of a bag with the bottom slit open and then tied again with a strong strap. In the top of the bag he inserted an iron hoop. This bag was lowered into a barrel of pickling solution until the top was just a little above the surface of the liquid, and it was held in that position by a small block and tackle. He poured the grain which was to be pickled into the bag as it hung in suspension in the pickling solution; every grain was covered with the liquid. He then pulled it out of the solution by means of the block and tackle and let it hang in the air. The bag in which he intended to convey the grain to the fields was placed over the bottom of the pickling bag and the strap unbuckled. Mr. Scales had grown crops which had been so badly affected with smut that he had to cut them for green feed. Speaking as one who fed stock with his hay, he said that he could not think of a more objectionable fodder than smutty hay, and he considered that it scoured horses, and so was injurious to them. Messrs. R. Hill and F. Pink stated that horses would eat and relish smutty hay in preference to clean hay, and it was not injurious.

CLARE (Average annual rainfall, 24-30in.)

Present: 22 members.

**MANURIAL TESTS.**—Mr. R. Hunter gave a brief account of experiments carried out by him last year in manuring fruit trees with potash. He explained that through various causes results were inconclusive, but he hoped that a further trial would be given this season by members. In reply to a question he said the application of the manures had a distinctly beneficial effect. Mr. Pattullo agreed to test applications of potash manures on pip fruits, and Mr. Hicks on peaches and apricots.

**PRESENTATION TO THE HON. SECRETARY.**—Members made a handsome presentation to the Hon. Secretary (Mr. P. H. Knappstein). Eulogistic reference to the energy and

ability of Mr. Knappstein were made by the Chairman (Mr. J. Dux) and Messrs. Pattullo, Hunter, Acate, Nolan, and Mr. C. E. Birks (Advisory Board of Agriculture).

#### GAWLER RIVER (Average annual rainfall, 17in. to 18in.).

June 8th.—Present : 12 members and three visitors.

**STOCK ON THE FARM.**—Mr. W. Roediger contributed a paper. Whilst a farm of 1,000 acres would carry a flock of 400 ewes, rearing 350 lambs, in addition to allowing 400 acres for hay and wheat and 350 acres fallow, and supporting 35 horses and 10 cows, he said, a farm of 500 acres could not be stocked to the same extent proportionately. The sheep he favored were Lincoln-Merino crossed with Lincoln. They were large framed, good mothers, and produced fine quality wool. He kept one class of sheep only, thus the wool was a uniform clip. On the above-named cross he used Dorset Horn and Shropshire rams. A good example was set by the Roseworthy Agricultural College in the way the sheep were fed and housed there. The animals should be frequently changed from paddock to paddock, even if to poorer feed. Fifty acres of rape, and the same area of barley, sown early under favorable conditions, would provide excellent feed. For hand-feeding oats would be found very satisfactory; 35 lambs would do well on 1bush. per day. Seven cows should return for butter, calves, and feed to pigs £100 per annum. Labor would cost £50 and extra feed £20, a net return of £30. Seventy summer lambs at 18s. per head would yield £63, labor would cost £13, and extra feed £16; a net return of £34 resulting. In this comparison it was assumed that the lambs were given 2bush. oats per day for three months, and were kept in a yard with a trough and box of salt provided.

**POULTRY.**—Dealing with this subject, Mr. Roediger said poultry should be kept in a small yard with house possessing a concrete floor. This should be cleaned daily; the excrement would be found very valuable in the garden. When tick had been troublesome he had sprayed the house with a mixture of 2galls. oil and  $\frac{1}{2}$ gall. kerosine, which had effectually destroyed the pest. Laying hens should be kept in a yard to themselves. Feed should consist of bran and pollard mixed with hot water in the winter mornings, with cut green feed, such as rape, lucerne, lettuce at midday, and wheat thrown into straw in the afternoon. Overfeeding should be avoided.

#### MALLALA (Average annual rainfall, 16-88in.).

July 6th.—Present : 10 members.

**SOWING AND HARVESTING WHEAT.**—Mr. D. F. Argent, in a short paper under this heading, said farmers should be careful to see that they sowed the wheat most suitable to the land they were cropping. The most popular varieties in this district were King's Early, Gluyas, and Baroota Wonder. These were good for both hay and grain. Gluyas, however, should not be put in on stiff clay soil. One and a half bushels of grain, with 100lbs. of super. on stiff clay, and 70lbs. to 80lbs. on dark land, should be sown. The grain should not be buried deeply, and care should be taken both in sowing and harvesting to keep the varieties separate. He would not pickle the seed in dry seasons, as the grain was more liable to malt. The majority of members favored Baroota Wonder as the best wheat for hay, as that variety could be left until it had grain in it and it would still retain its color. Some, however, favored King's Early. Members generally did not agree with Mr. Argent that wheat was more liable to malt when pickled, as their experience had been otherwise. It was generally agreed that Gluyas was the best wheat to sow for reaping where the ground was level. In answer to a question, Mr. Argent said he always pickled his wheat in a wooden tub with a windlass attached to lift the bags in and out.

#### RIVERTON (Average annual rainfall, 20-48in.).

June 23rd.—Present : 17 members and two visitors.

**FALLOWING.**—A paper on this subject was read by Mr. W. E. Blatchford. Fallowing was absolutely essential to successful farming in this district, he said. Early fallowing should be done with a plough cutting five 7in. furrows. Red land should be broken to a depth of 4in.; from 3in. to 4in. would be found sufficient in black soil. The work should be completed by the end of August. Clay would set hard if ploughed too wet. This could be obviated to a certain extent by burying part of the stubble. If half an inch of rain fell in September the harrows should be put over the land. At the end of September, when the weather became more settled, the cultivator could be used, and following this the scarifier harrows, to destroy stinkwort, &c. The use of light harrows every wet day would assist in the conservation of moisture. Rough land should be gone over with the rib roller in February or March. Mr. Phillips preferred fallowing in July; there was then rubbish to bury which would benefit the land. Mr. W. S. Kelly said summer fallowing was a help if a wet winter followed, as the work was completed

earlier. To neglect to work summer fallow directly after seeding was to court disaster. Mr. H. A. Davis would fallow black land to a depth of 3in. With early rains the rubbish germinated quickly on summer fallow, which should be left slightly rough. Mr. J. McInerney thought land which was fallowed early and then worked up late failed to retain the moisture. Mr. J. W. Kelly used the disc plough on his sandy and firm land, burying the stubble, and as a result his returns were generally 4bush. or 5bush. better than otherwise. This implement, however, was not suitable for use in black or heavy soil. Mr. H. C. Thomas last year sowed 20 acres of barley in September and it yielded 25bush. to the acre. Mr. W. S. Kelly had sown barley, with a good dressing of manure, on part of his summer fallow. The land, when worked up, appeared to be in good condition, but portion cut about 1 ton to the acre, the remainder of the crop failed.

At the previous meeting, which partook of the nature of a social gathering, addresses were given by Mr. F. E. Place, B.Sc., M.R.C.V.S. (Government Veterinary Lecturer), and Mr. D. F. Laurie (Poultry Expert).

**SALISBURY, May 5th.**—Mr. Bagster gave a further demonstration in knotting and splicing ropes.

**STOCKPORT, July 9th.**—It was reported that 12 sheep had died as the result of eating soursobs that were in flower. Some of the members considered the soursob good for fattening sheep.

## YORKE PENINSULA DISTRICT. (TO BUTE.)

MINLATON (Average annual rainfall, 17·4in.)

July 11th. —Present: 14 members.

**THE FARM HOMESTEAD.**—Mr. R. H. Tillbrook read a paper as follows:—“After purchasing an unimproved farm the first point to decide on is the erection of the homestead. This should be built on rising ground near a main road, and in a good position to view the farm. The house should be built of stone, having high walls and plenty of ventilation. Equal thought should be given to laying out the farm outbuildings. These should be placed well away from the house, and always at the back. Nothing spoils the appearance of a well-built farmhouse as much as unsightly sheds built about the front and sides of the home. Assuming that the farm comprises about a thousand acres, the stable should be big enough for at least 16 horses, with a couple of loose boxes also, and should be built of stone with an iron roof. By placing the stable and chaffhouse under the one roof one saves money and the arrangement is more convenient. The hay yard should be close behind the stable and enclosed with a stone wall 4ft. high. The implement sheds and barn should be at least a hundred yards away from the stable. It is not advisable to have all sheds connected owing to the danger of fire. If the barn is constructed with an entrance at both front and back, with a gable roof, a lean-to on either side would provide a good implement shed, blacksmith shop, &c. It is a good plan to have sliding doors in front of the implement shed, so that implements can be put in and out without much trouble. Water for the stock should be as handy to the homestead as possible and always available. I prefer wide gateways with gas piping gates. Good sheep-proof fences help to make good neighbors. As time goes on trees should be planted around the house, but not near enough to interfere with the garden or underground tanks.” Most members thought the homestead should be built some distance back from the road, so that the farmer could keep pigs, fowls, &c., without causing his neighbors annoyance. It should be close to the water supply. The implement shed should be lofty, with gable ends, iron roof, and sliding doors on both sides, so that the implements could be taken right through.

**TELEPHONE ON THE FARM.**—Mr. Correll, in dealing with this subject in a paper, said every up-to-date farmer should have his homestead connected with the telephone. This would enable him to quickly get in touch with business firms, and at harvest and seed time, or in case of accident, it would prove invaluable. A private line between two or more parties could be erected by fastening a cheap button insulator to an ordinary fencing standard and attaching the standard to a fence, so that the wire was about 3ft. above the fence top. On either side of roads poles should be so erected as to prevent the wire being less than 18ft. above the centre of the roadway. He gave the costs and charges of the Telegraph Department in connection with this matter.

**PINE FOREST** (Average annual rainfall, 14.15in.).

July 7th.—Present: 10 members and three visitors.

**POULTRY.**—Mr. W. Attenborough read a paper on this subject. He mentioned the development that had taken place in the industry during the past 20 years, and instanced a case where the returns from poultry had been much greater than those from cows on a particular holding. For table purposes, he did not favor very large birds, as the meat of these was inclined to be coarser, and the cost of feeding was greater. Local poultry-raisers were at a disadvantage in rearing table birds, in that the distance from market was so great.

**YORKETOWN** (Average annual rainfall, 17.47in.).

July 2nd.—Present: 16 members and one visitor.

**POULTRY.**—Mr. F. Emmel read a paper. After referring to the development of the industry, and the suitability of the climate of the State for poultry-raising, he said that to obtain the best results from poultry it was necessary to feed and house them well. Houses of galvanized iron and sawn timber free of cracks, 7ft. long, 8ft. high at the front and 5ft. high at the back, would accommodate from 20 to 25 hens. Fowls roosting in trees utilised all their energy in producing bodily warmth, consequently little was available for the formation of eggs. For egg production the White Leghorn was a good breed, and for general purposes the Silver Wyandotte or Black Orpington was recommended. Water should be kept in a well-shaded position, and an 8in. flower pot would be found a most suitable vessel for this. The house should be cleaned three or four times weekly, a sharp lookout being kept for vermin. Sickly birds should be immediately removed from contact with the flock. Grain should be fed morning and evening, and twice weekly a crumbly mash of bran, pollard, and meal should be given to supply albuminoid. In answer to questions he stated that a poultry house should face the east, and should be partly enclosed in front in summer to give shade from the morning sun. In order to give the birds exercise, either the scratching system should be adopted (that was to say about 6in. of straw and rubbish should be kept on the floor of the fowlhouse) or a fair-sized yard provided for the fowls to run in. Chickens should never be allowed to run with the older fowls. It was imperative that clean fresh water should be given every day. He thought it a good plan to put straw on the fowlhouse in winter, as it helped to keep the fowls warm.

**DOWLINGVILLE**, June 5th.—Members agreed that the present system of handling wheat was too costly, and decided to secure information regarding handling in bulk.

**KADINA.—DEMONSTRATION PLOTS.**—The demonstration plot committee reported that the plots on which the Branch was conducting manurial and quantity of seed tests showed a fair growth.

**WESTERN DISTRICT.****BUTLER** (Average annual rainfall, 16.61in.).

July 7th.—Present: 16 members and 27 visitors.

**HOMESTEAD MEETING.**—The meeting was held at the homestead of Mr. G. J. Parker. A five-acre plot of peas and three acres of turnips appeared to be doing well, and the horses and cattle feeding in a paddock of rye and lucerne were in good condition. Fruit trees also presented a healthy appearance. A hand-made blower and forge came in for considerable attention, and a dam, which had only been empty for a short time once during the last eight years, was noticed. Reference was made by members to the many acts of kindness which the host and hostess (who were the first settlers in the district) had performed.

**CARROW.**

July 2nd.—Present: five members and five visitors.

**CULTIVATION IN NEW AREAS.**—Mr. W. L. Burt contributed a paper on this subject. Too frequently, he said, large areas of mallee were rolled and the crop hurried in, with consequent poor results. If the land were carefully cleared of rubbish and sticks the growth of the crop would be better, and the stubble burn would be much more satisfactory. One hundred acres well put in would be found much better than 200 acres farmed in a slipshod manner. New land should be cropped for three successive years, the stubbles being either burnt or fire-raked. There would then be few shoots to contend

with. Cross ploughing would destroy surface roots of the stumps. Shoot-cutting should not be delayed, this should be done regularly, and the plough then put through the land to a depth of 2in. or 3in., crossing the last year's work in each ploughing. Mr. J. E. Matthews agreed that continuous cutting was the best method of destroying mallee shoots. Ploughing to a depth of from 2in. to 3in. would effectively root up stumps. Mr. F. Beare advocated fire-raking for destroying shoots. Mr. W. D. Chalmers found disc ploughing a good means of killing the shoots. Mr. H. A. Freeman advised cutting the shoots in December or January, when the sap was up. It was difficult to crop the same land continuously on a new holding until there was sufficient land cleared to provide feed. Ploughing to a greater depth than 2½ins. turned up too much of the subsoil, which took a considerable time to sweeten.

#### ELBOW HILL (Average annual rainfall, 11in. to 12in.).

July 4th.—Present: 11 members and two visitors.

**POULTRY ON THE FARM.**—Mr. F. Freeth read a paper. Fowls on the farm, he said, were generally kept at a loss. This should not be the case. They should be housed at night; a suitable structure for 100 laying hens being 30ft. long, 9ft. wide, 7ft. high in front (it should face the east), and 6ft. at the back. The yard should be foxproof, 6ft. netting being placed 6in. in the ground. The front of the house also should be netted to prevent crows taking the eggs. Bran and pollard should be fed first thing of a morning; at 11 o'clock chaffed greenfeed should be supplied; and at 4 o'clock wheat and a little crushed maize. Clean water in earthenware vessels should always be available, and a little permanganate of potash should be added to this once a week. A good supply of grit, consisting of equal parts of coarse sand, old mortar, and shells should be available; and a piece of ground should be turned over for the birds to scratch in. For laying hens, boiled meat was splendid feed. He would not confine his attention to one breed, but would keep White Leghorns and White and Black Orpingtons. Wyandottes were inclined to lay eggs that were on the small side. Nests should be placed in well drained places. Eggs for hatching should be of medium size. Chickens should be given plenty of good food. Old hens should be culled out. The breeding stock should be selected and then placed in a separate pen at least 21 days before breeding commenced. Mr. H. Wheeler thought the Silver Wyandotte a good fowl for the farm. Mr. Zerk thought fowls that were confined were more subject to disease than those allowed freedom. Mr. W. T. Cooper (chairman) thought the White Leghorn the best all-round fowl for the farm. He advised feeding wheat on a heap of chaff. Mr. Jacobs said it was a mistake to breed from young birds. Mr. Brooks thought too much attention was required when the birds were housed. The Hon. Secretary (Mr. G. F. Wake) advised keeping a few fowls and looking after them well. The male bird should be changed frequently.

#### ROBERTS AND VERRAN.

July 7th.—Present: eight members.

**FARM MANAGEMENT.**—Mr. F. Masters read a paper. He said in new country feed for working horses is the first essential; and, remembering the cost of transit, one needs to carefully study the prices of the various foodstuffs. Good hay chaff, say, mixed wheaten and oaten, is preferable; but if the best value is to be got from this, bran should be fed to keep the horses' systems in good order. An occasional addition of molasses and oats as deemed necessary to supply variation and strength should be made. Taking present prices of hay chaff and bran, £4 per ton and 1s. 4d. per bushel respectively, the substitution of a portion of the chaff by bran will be found to pay, and the total feed bill will be less. Oats, this season, are selling at 1s. 6d. per bushel, therefore it would prove remunerative to substitute as much oats as possible for the chaff. Of course, the grain ration is heating, and bran must be resorted to to keep the horses in good health. On a new farm stumps and shoots are frequently responsible for heavy expenditure. For working the ground the share gang plough is excellent; but as a shoot-cutter it cannot be compared with the disc plough; hence, looking at the position all round, the plough which works the soil equally as well and cuts twice as many shoots is the more economical to use. The wear and tear on the disc plough may exceed that of the share plough; but this is more than counterbalanced by the shoot-cutting saved. When fallow comes into the routine of a new farm this will soon have its annual crop of weeds which make it necessary to have a means of getting rid of them as cheaply as possible. No implement yet invented compares with sheep as a weed eradicator on our fallows. No farm can be as successful as that which maintains its flock, large or small, and no money invested upon the farm in any other direction will return the same interest as that invested in sheep. The capital thus employed is always realisable. The animals require scarcely

any working plant and no labor, which cannot be said of any other farm investment. With stock generally the best is the most economical, and the sooner the farmer secures quality therein the better. The same applies to seed. It is hard to estimate the actual loss to the farming community due to carelessness in regard to the quality of the seed sown. It certainly pays to get the best seed, keep the best seed, and improve it by selection. One of the bugbears of the farmer is the cost of labor. This, on a new farm, is accentuated by the comparative low returns in its early stages. What is possible with a 20bush. crop is not possible with a 10bush. crop, and less still can be paid on a 6bush. crop; and it appears to me that, generally speaking, the greatest net result is to be obtained from one's own labor. Oiling of harness lengthens its life. Attention to greasing or oiling wheels and protecting them and bearings from sand are some of the economies that might be practised. The self-contained farm, on which the most of what is needed for use and consumption is grown or produced, is the ideal. Therefore, the farmer should produce his own hay, fodders, beef, mutton, butter, bacon, poultry, eggs, and milk. Members agreed that farming would be more profitable if attention were paid the various matters suggested in the paper.

### SALT CREEK.

July 4th.—Present: 15 members.

DAIRYING.—This subject was dealt with in a paper by Mr. J. T. Jacobs. "It is being recognised throughout the State," he said, "that to depend on wheat-growing alone in the drier districts is rather too precarious a means of getting a living. Every year in the North, and in the Murray districts, the practice of keeping a few cows is becoming more general, and many farmers who had almost given up hope of retaining their holdings have, by giving a portion of their attention to dairying, been able to at least make ends meet in spite of the failure of their wheat crops. In this district practically every farmer keeps a few cows with the idea of supplying his own household with milk and butter, and I maintain that the labor, &c., involved would not be so much more if a few additional cows were kept, so that after supplying household requirements there would be a considerable surplus to send to market every week. If, say, six to eight good cows were kept they should, if properly managed, make enough butter to pay the store bills of most families on a farm, besides which considerable profit could be derived from feeding the separated milk to calves and pigs. I might, at this juncture, mention that in feeding separated milk to calves care should be exercised to always skim the froth off the milk. In case of a calf having missed one meal, do not allow it too much. I have known separator milk to cause the sudden death of a calf which had become very hungry and then had access to an unlimited supply. The most popular objection to cows seems to be that they are regarded as too much of a tie by the average person, but where there are large families I do not think there should be much sacrifice of freedom if all the members of the family are able to milk. I strongly believe that the boys especially should be able to milk. Even if it is not necessary for them to help with this work, as a general rule, it is very nice for them to be able to relieve the women folk of the necessity for going out to the cow yard in wet or stormy weather. Good cows only should be purchased. It is the progeny of the original cows that compose the future herd. Have them to come into milk at a suitable time of the year; April is about the best in this district. Always milk at regular hours, and milk quickly, quietly, and thoroughly. A good plan to ensure cleanliness is to keep the hair on the cows' udders around the teats clipped, and brush the udder with a soft brush before milking. No modern farmer would think of conducting a dairy without a separator. This should be kept perfectly clean and well oiled. The operator should make sure that it is evenly balanced and turned at the nearest possible speed to that advised in the directions. No machine will abstract all the cream if these points are overlooked. It also pays to market butter of good quality and attractive appearance. When separating never allow the warm cream to run into a vessel already containing cream from a previous separating. Allow it to stand for half a day before adding, then mix it thoroughly with a clean stick or a wooden spoon. No fresh cream should be added for 24 hours before churning, as good butter cannot be made from cream varying in degrees of ripeness. In summer a little salt added to cream will keep it in better condition, but preservatives should not be used. Keep the cream stored in a cool and well-ventilated cupboard away from any articles of food or household use, as cream is a great absorbent of odours, to the detriment of the quality of the butter. When making up the butter after churning, wash it several times in cold water and work out all buttermilk, but do not overwork it, as the texture of the butter may be spoilt and rendered greasy. Butter made from scalded cream will also be found to have this disadvantage."

**YADNARIE** (Average annual rainfall, 14-09in.).

July 3rd.—Present: 12 members and eight visitors.

**HANDLING WHEAT IN BULK.**—After reading an extract dealing with the bulk handling of wheat, Mr. W. L. Brown said he thought this State would be well advised to continue the present system of handling grain. Mr. A. Spriggs and Mr. B. B. Crosby concurred. Mr. J. J. Deer and Mr. H. L. Bauer thought the quantity of wheat exported from this State did not warrant the expense of erecting elevators. The Chairman (Mr. S. H. Pearce) agreed. Mr. P. Allen thought the farmer would lose if the system were introduced. Members thought small quantities of pickled grain could safely be fed to horses; it was preferable to boil the grain before using it in this way, however.

**YALLUNDA** (Average annual rainfall, 18in. to 19in.)

July 4th.—Present: 12 members.

**LUCERNE.**—Mr. A. V. Teakle read a paper. Land for this crop should be ploughed to a depth of between 9in. to 1ft., he said, and subsequently worked down to a fine tilth. It should be dressed with stable manure for preference, or in the absence of this, bonedust or bone super. Sowing should be done in early September, the seed being broadcast as evenly as possible. Drilling would result in the seed being buried too deeply. Following sowing, the land should be gone over with a brush or log. Two acres of lucerne under irrigation would feed four or five dairy cows through the year, and also provide summer greenfeed for poultry. For lamb-raising and fattening wethers it was unequalled. This would be a considerable offset against the cost of a well and engine or mill, which would be found essential for lucerne-growing in this district, where there was no natural supply of water available. Mr. W. Cabot a few years ago sowed a few pounds of lucerne seed with his grain crops; a few plants were growing. Mr. Provis had some plants in a garden and under pepper trees; they had been there for 20 years or more and made good growth. Mr. Walsh, some years ago, had sown 3lbs. of lucerne per acre with oats on rather heavy low-lying ground. It had not done well. The Hon. Secretary (Mr. J. W. Winch) had noticed that lucerne on low-lying ground had not been successful unless the land was drained.

**COORABIE, July 4th.**—**DESTRUCTION OF RABBITS.**—Mr. Muegge introduced this question, and stated that in consequence of the shortage of feed and the resultant comparative scarcity of rabbits, the time was now opportune to make a combined effort to eradicate this pest, and he suggested that the Branch approach the Local Vermin Board, asking them to enforce the Vermin Act as applying to the compulsory destruction of rabbits. It was decided that the Hon. Secretary should communicate with the Vermin Board in connection with this matter.

**GREEN PATCH, July 6th.**—Members reported having noticed increased numbers of foxes in the district. It was generally thought that by destroying rabbits they would do more good than harm.

**PENONG.**—**STOCK TROUBLES.**—Mr. A. Shipard delivered an address dealing with the treatment of stock ailments. He referred to different methods he had adopted in treating his animals.

**EASTERN DISTRICT.**

(EAST OF MOUNT LOFTY RANGES.)

**BORRIKA.**

July 4th.—Present: 25 members and several visitors.

**HAY OR GRAIN.**—Mr. H. J. Richards, in a paper, discussed the relative returns from cutting crops for hay and harvesting the grain. He took as an instance an area of 25 acres. "A 10-bush. return from this," he said, "would be 250bush. of marketable wheat at 3s. 3d. a bushel. The gross return being £40 12s. 6d. A 10-bush. crop will cut somewhere near a ton of hay to the acre, providing the right kinds of wheat, as Dart's Imperial, Yandilla King, Marshall's No. 3, Baroota Wonder, or any other varieties that will grow a fair amount of straw are sown. We can value the 25 tons of hay at £2 a ton in the field, giving a return of £50; the difference between the hay and corn values being £9 7s. 6d. The object of this paper is to find out whether it really pays to cut hay or leave the crop

for corn. Bran and pollard can be bought for £5 a ton; the value of corn as stated is £40 12s. 6d., so for that amount a farmer can buy 8 tons of bran and pollard. That, with the cocky chaff from the harvest, will keep a team of six horses for 200 days. A six-horse team will consume three-quarters of a ton of chaff a week, or perhaps a little more; at that rate 25 tons of hay will last the team 233 days, but in order to be on the safe side, say 221 days. So far the gain is with the hay crop, the feeding value being three weeks longer than that of the corn. But with hay chaff the farmer needs more machinery, such as a binder, chaffcutter, and horseworks. Cutting the chaff will cost 5s. a ton; interest on the extra capital will amount to something like £6, including wear and tear, making the cost of the hay feeding £12 5s. more. Cleaning the corn and finding bags will cost £4 11s. 1d. The hay will involve £7 9s. 6d. extra for handling; for that amount 1½ tons more bran and pollard can be bought, making the corn last 37 days longer. Thus the figures stand—for £48 2s. worth of bran and pollard, with cocky chaff, we can feed the team for 237 days. Hay feeding costs £62 5s. for 221 days, giving a profit by reaping crops and a saving in the handling. I have not dealt with the cost of binding or carting the hay against stripping the corn and carting the cocky chaff, or in other words, the waste from our harvest, as I think the costs will be very nearly equal. Feeding with bran and pollard, therefore, seems to me to be the cheaper." Mr. Seary thought it not worth while cutting a crop that would not yield ½ ton of hay per acre. A 1-ton hay crop was more profitable than a 10-bush. grain crop.

**HORSES.**—In a short paper on this subject, Mr. G. Stephens said the best horse for this district was the progeny of the light mare and the draught horse with a good body and light legs. Mares should not be put to the stallion until the 14th day after foaling. Sore shoulders would not be troublesome if well-fitting collars were used. He advised placing three tablespoonfuls of sulphur in each animal's feed once a week in the summer. A few drops of machinery oil under the chin of the horse would discourage the attack of botflies. Mr. Seary favored mating the draught horse to a light mare. The Chairman (Mr. V. V. Brown) said oil or kerosene would keep botflies from troubling the animals.

#### CLANFIELD (Average annual rainfall, 16in. to 17in.).

July 4th.—Present: 12 members and five visitors.

**MACHINERY AND IMPLEMENTS.**—Mr. L. Orwell read a short paper. Suitability to local conditions, he said, should be studied when implements, &c., were being purchased. A careful watch should be kept on wearing parts, and nuts should be kept tightly screwed, thus obviating needless friction. Binders, harvesters, strippers, drills, &c., should be painted every two or three years. Where stumps were encountered a strong plough should be used. In this district a 16 or 17 disc drill would be found large enough. The wheels should have adjustable spokes. The binder should, where possible, be used for hay-cutting; this would economise labor, and the hay was better for chaffing. The harvester was the most suitable machine for use in flat country; but on sand ridges, the stripper, on account of its lighter draught, would be found best. A suitable plant for chaff-cutting consisted of a No. 4 chaffcutter and a five or six horse-power engine.

#### CLAYPAN BORE (Average annual rainfall, 16in. to 17in.).

Present: eight members and one visitor.

**FARM BUILDING.**—The Hon. Secretary (Mr. L. McCormack) read a paper as follows:—"In dealing with this subject I have endeavored to outline a scheme of laying out and erecting farm buildings, which to my mind should appeal to the settler who intends establishing a home and wresting a competence from the mallee. The first consideration should be the selection of a suitable site for a homestead. It should if possible be centrally situated on the block in order to ensure expeditious working. Other factors should also be borne in mind, the most important of which will be good drainage and good quality soil—the latter with the view to establishing a garden and orchard as well as growing fodder crops within easy reach of the homestead. Too much care cannot be exercised on the foregoing, as the home is to be the hub of the farm, and from it will extend all future operations. Having selected the site one should now proceed with the erection of the homestead. Wherever possible this should be built of stone, and the most suitable style in this climate is a bungalow, or at least one with a verandah on all sides, as either will ensure a several degrees cooler residence during the summer than any other type of building. However, I recognise that in most cases in this district stone is not easily procurable, and if such is the case—and seeing that lost time is a serious item during the pioneering days—I would recommend the first homestead being built of iron; this could eventually be turned to another use, and either stone or brick procured for the building of a permanent home. For other buildings the class of material is not so important.

For this district I recommend galvanized iron. Not only is it quickly erected, but most out-buildings can be built by a person without any expert knowledge of carpentry, thus effecting a large saving in cost of erection. For ordinary purposes I prefer a stable with a gable roof and closed on the north, west, and south sides. If there is sufficient drainage this will ensure both warmth and dryness, which are essential in the housing of stock. Stables facing the south should be avoided, as they never get any sunlight directly inside, and are consequently very damp during winter. If stalls are provided they should be 5ft. 6in. or 6ft. wide, but where economy is essential and horses are accustomed to feeding together they are not altogether necessary. The most useful class of manger is one at least 3ft. deep (for feeding loose hay, of which I am an ardent advocate), with small feed boxes, at intervals, for each pair of horses. These may be used when hay, chaff, and corn is being fed. A fairly large post and rail yard should be attached to the stable so that the freedom of the horses is not restricted. A clean patch of sand should be provided, in which the animals can roll at pleasure. An essential to every stable is a good crush pen, in which to catch and handle colts and even quiet workers, who will oftentimes not allow one to effectively dress accidental wounds, &c., unless put in the crush. In order to facilitate feeding, haystacks and chaffhouse should be in close proximity to the stable. If built at the back or either end they can be placed under the same roof, thus effecting a saving in material. I favor the engine chaffcutter and chaffhouse being placed in a continuous line, the chaffcutter shed having the side next the stack, fitted with sliding doors. This shed can then be easily kept full with hay, so that it is always ready for chaffing even when hay from stacks is too wet to cut. Sliding doors may be thrown wide open during the summer, thus obviating the dust nuisance. I have found sliding doors, and even gates where practicable, have almost double the life of those hung on hinges. A barn, with implement shed attached, is still another necessary building, in fact one of the most essential. I do not intend to lay down any hard and fast rules as to either style or size, as each one should be guided by his own requirements. However, having experienced the loss occasioned through both implements and seed being not properly covered, I am confident that the annual loss is far greater than the interest on the cost of building. The implement shed should be built without any central uprights, so that harvesting and other implements which are only taken out of the shed once a year can be stacked closely together, thus saving at least 50 per cent. of the floor space. All the buildings which I have enumerated are really necessary for the economical and expeditious working of the farm, but as they entail a good deal of expenditure it is hardly likely that the beginner will be able to build the lot at once. If such is the case a great deal of foresight is necessary when erecting improvements by instalments. Care should be taken that they are done in such a way that additions can be effected without spoiling the appearance of the original structure; in fact it is not a difficult matter, and is certainly a very wise one, to draw a rough plan of the ultimate intention, and work accordingly." Mr. D. McCormack objected to haystacks being very close to stables and sheds owing to the risk of fire, which if once started would make a clean sweep of all buildings. He preferred carting hay to the cutter, the chaffhouse being adjacent to the stable. Mr. M. Robinson said the writer had outlined a fine scheme of farm buildings. He had overlooked, however, the provision of water for stock and irrigating purposes. In this district, where subterranean supplies were available, it was advisable to have a bore and storage tank in a well-elevated position so that water could be reticulated wherever required. Mr. Jno. Gray thought it advisable, if possible, to have all out-buildings on the east side of the residence, when there would be very little trouble from dust arising out of the traffic of stock. A good large windbreak of natural timber should also be left around the homestead. He favored a stable facing the south-east if possible, but sometimes this was not good owing to the fall of the ground. He considered the south the best alternative. It was very convenient to have stacks close to the stable, but, owing to the risk of fire, it was wise to have a good proportion of the hay stacked at a safe distance. If the manger suggested by the writer were used the stable would have to be built with stalls, whilst if horses were not in stalls chaff could be placed all along the manger.

COOMANDOOK (Average annual rainfall, 18·0lin.).

June 6th.—Present: 14 members and three visitors.

MALLEE SHOOT.—Mr. Chapman read a paper. The scrub, he said, should be rolled early, say September. The stumps would then carry a fair growth by February or March, when the scrub could be fired; this would severely check the shoots. A good scarifier should then be put over the land to a depth of 2in. or 3in. This implement stirred the soil to a more uniform depth and left no ridges, as was the case with the disc

implement. The wheat selected should be a good straw-yielding variety, or oats could be sown, in order to secure a good burn in February or early March, which was of great importance. After a light ploughing the land could be sown the following year with good prospects of a fair crop and stubble burn, after which it could be used for grazing. If the farmer failed to secure a good stubble burn the first year he advised fallowing the land with a strong, fairly high-framed implement with room between the standards to allow stumps to pass through. If heavy land, it should be ploughed to a depth of 4in., and if lighter, 3in. With fair draught about one-half the stumps could be dragged out. These could be raked into rows and then cross-raked into heaps. The result of the fallowing should ensure a good stubble burn. Members favored the use of the scarifier after the burn, and thought Golden Drop the best wheat to sow, as it was a good yielder of both straw and grain.

#### COONALPYN.

July 3rd.—Present: nine members and three visitors.

**HORSE-BREEDING.**—Continuing the discussion on the paper read by Mr. Wall at the April meeting (see page 1100, May issue), Mr. Venning strongly favored the Clydesdale as the most useful stamp of farm horse, and emphasised the fact that in these new mallee lands it was useless to attempt to rear a foal unless one could be sure of having abundance of nutritious food for the animal after the weaning. Breed, he said, was no good without feed. He would not object to breeding from an animal with white points. Most members favored dark hoofs. Mr. Cronin thought there would be no bother with hoofs, whether white or black, breaking away if they were regularly trimmed. He favored the medium draughts. Mr. Wall, in reply, said he did not like too much blood in a farm team; such horses were often too flighty and apt to fret while at work. He preferred the clean-legged, active, medium stamp. In reply to a question, he stated that horses bred locally thrived much better than those brought from other places.

#### CRESSY.

July 7th.—Present: seven members.

**FENCING.**—In a short paper on this subject Mr. J. T. Johnstone emphasized the necessity for preparing for sheep keeping by erecting fences to which netting could be attached without difficulty. He preferred red gum posts set two chains apart with angle irons between. The posts should be 3ft. 6in. high, and bored for six wires in such a manner as to enable 3ft. wire netting to be affixed, the latter being countersunk 2in. in the ground. Mr. McCabe thought the posts should be not more than half a chain apart. Flat iron posts were more suitable than those of angle iron. For the first few years a single barb should suffice. Mr. Lee favored angle iron posts. Mr. Angas supported red gum posts one chain apart, with three or four T iron droppers between. These held better in the sand. Six inches of the netting should be buried, 4in. at the bottom being turned in an outward direction.

FORSTER (Average annual rainfall, 10in. to 11in.)

July 11th.—Present: seven members.

**MIXED FARMING.**—Discussing this question Mr. J. Searle said sheep would be found more profitable than cattle, as they not only cleared up weeds more thoroughly, but destroyed shoots and bushes. He objected to the practice of growing crops on the fallow. Mr. T. Searle would not keep much stock of any nature on a scrub block; he preferred to have the fallow lie idle. Mr. Powell thought cows would not pay; but fowls were profitable if well cared for and protected from winds.

**RIVALRY.**—The paper on this subject read at the Naracoorte Branch meeting (page 1231) was discussed. Mr. T. Searle thought good would follow the suggestion that harvest returns should be discussed. Mr. W. Searle mentioned that land which he harrowed before the drill returned a better crop than that harrowed after. Mr. C. Hayman advised harrowing after the drill; this enabled the wheat to get ahead of the weeds.

#### HALIDON.

June 3rd.—Present: 19 members and two visitors.

**INAUGURAL MEETING.**—The inaugural meeting of the Branch was attended by Mr. H. J. Finnis, of the Department of Agriculture, who addressed the gathering on the aims and objects of the Bureau, and mentioned definite lines of work which the Branch could undertake. Stress was laid on the value of experimental and demonstration plots, especially in new areas. Mr. Braithwaite undertook to conduct on his holding tests with different quantities of super., and plots for this purpose were selected and laid out.

**SEEDING OPERATIONS.**—Owing to three weeks' dry weather many members were in doubt whether to sow lest the wheat should malt. Mr. Russell considered that those who still had any quantity to sow had little option in the matter, for if they did not sow now it would soon be too late to sow at all. He was drilling his wheat as shallow as possible, and would harrow when the rain came; this would cover any exposed seed. Under these circumstances he did not think much wheat would malt. Some of his land was heavy and some light. Mr. Muecke considered it dangerous to sow in the heavier soils; but Mr. Harris thought the sandy soils which still retained a considerable amount of moisture the more unsafe. Members agreed that it was now too late to sow "late" wheats.

HALIDON (Average annual rainfall, ——.in.).

July 8th.—Present: 11 members and three visitors.

**MANAGEMENT OF FARM HORSES.**—Mr. J. M. Braithwaite read a paper. He said—"There is a great deal of difference of opinion as to the best type of horse for work in the mallee. One person prefers a horse of 17 to 18 hands, large in body and leg; another favoring the animal of say 16 hands, and of the lighter breed. The ideal horse for my class of farming is one of about 16 hands, say, from a heavy draught mare with plenty of bone and a thoroughbred stallion. In this cross one should get plenty of bone, and an animal well topped up; one that can be put into any implement. One must not forget to have one or two heavy horses for dray work. The unfortunate part for the new farmer is that he has not the money to put up stables or rail yards. I would prefer not to have any wire about a horse yard, but what can one do when one cannot get rails? A horse should have a good roomy stable, or shed with stalls, say 8ft. by 7ft., with the open side to the east so that he gets the first warmth of the sun. This is rather an important point with horses, for, in my opinion, a horse does not get into full working order until, say, 9 a.m. in the winter months if he is kept in an open yard, and no amount of shouting will get him moving until his blood is properly circulating. In the majority of cases the farmer runs a barbed wire round a few mallee stakes and calls it a stable yard. How some people get the work out of their stock is a marvel to me. To get the best out of a horse one must feed him well. In the first place get the best chaff available. If one is growing and cutting one's own, mix in the stack, say, 15 per cent. to 18 per cent. of oats that are not quite ripe. This mixture, when chaffed out, will give quite enough oats. In my opinion feeding an extra quantity of oats with the ordinary chaff is not suitable for the Australian horse, or, as I have seen some people do, feed cocky chaff and, say, 20 per cent. of oats. Cocky chaff is merely a filler-up and the horse does not derive any strength from it. If oats are fed at all they should be crushed or rolled, as most horses are given to bolting their food and do not derive the full benefit from it if it is not rolled or crushed. Bran is very good when used properly. It should not be given *ad lib*. The best general food is the ordinary hay chaff with about 18 per cent. of oats when chaffed at the same time and with a handful of molasses added. A little molasses or linseed every few days keeps the skin free and gives the horse a good coat. A horse should be fed in the morning at least one and a half hours before he is taken out to work. This gives him time to properly masticate his food. At mid-day he should have one and a half hours in which to feed and cool down. I do not approve the idea of taking nosebags out into the paddock and only giving the horses two drinks per day. The majority of people do not take into account that a horse requires at least 8galls. of water per day to digest his food and allow for the sweat and absorption of the inside tissues. Each animal requires at least 40lbs. weight of good chaff per day. This keeps a horse in good condition and in good working order, and is the amount of food my team is getting at the present time. It works out at a cost of about 1s. 1½d. per head per day. To feed a great quantity of oats and bran in this climate is certain to bring on sore shoulders and sores where the chains rub. The question of water is a vexed one with many people. I am of the opinion that the proper place for the water-trough is where the horse can get a drink night or day. If a horse is sweating much I prefer to let it have, say, half a bucket of water and then feed for a short time, after which it can return to the water. The ideal method would be to have a trough of fresh water alongside the food box so that the beast could drink when he thought fit. To have the trough outside the yard and allow the horse to drink his fill is looking for trouble in the shape of colic and other complaints of a like nature. Catching up and harnessing should be done quietly. We do not realise what a kind word means to a horse. I believe in being absolute master in the yard and let the stock know it when it is necessary. Grooming is a most important point in the health of the team. To start with the brush at the animal's nose and finish at his feet, and put in plenty of elbow grease, is the way to keep a horse fit and well. A good hard dandy brush is all that is required. Do not use a currycomb on any account.

Brush the shoulders well. Look inside the collar to see that it is clean and soft. If there is any dry sweat or loose hairs on the stuffing scrape it or brush it off. See that the collars fit well and that the horse's mane is clear. There is nothing that will give a horse sores quicker than to have a few long hairs out of his mane where the collar takes up the weight of the pull. When the horses are brought in at night look to their shoulders and rub the hand gently down them. If there is any signs of a scald or sore attend to it at once. A good plan when first starting with heavy work, such as ploughing or harvesting, is to wash each horse's shoulders with a little salt and water. This has a tendency to harden the skin, but nothing can prevent a horse scalding if his collar does not fit. Personally, if I could get men to do it, I would have every horse groomed down at night whether he was working or not, as there is nothing that freshens a horse up so much as being rubbed or groomed down. The English draught horse is groomed down night and morning, and the men look upon it as part of their work." Mr. von Doussa said that whilst there was nothing better than a good warm stable for horses, he thought that rugging was an excellent substitute. Besides keeping the horse warm and comfortable, it kept him with a good sleek coat, which in turn maintained the animal in good health. Grooming was made much easier and the chaff bill was saved. Mr. Weste did not agree with the writer in allowing the horses free access to water. He explained that the horse's digestive system was about the simplest of any animal. His stomach only held a limited quantity of food. If the horse drank with a full stomach the water washed the undigested matter into the bowels and it was passed out only partly digested. He held that the trough should be kept away from the horses, and the horses watered four times a day before meals. Mr. Chambers thought 40lbs. of chaff insufficient for all horses. He gave his horses as much chaff as they would eat. Some ate more than others. For sore shoulders he recommended mutton fat and blacklead on the sores and keeping the collar clean. The Hon. Secretary (Mr. W. F. D. Clarke) suggested bathing the shoulders with wattle-bark solution as a preventive of sore shoulders. A visitor thought that Australian horses could stand heavy feeding of oats if they became used to them gradually. In reply, Mr. Braithwaite said that the only objection he had to rugging was that if a horse was accustomed to being rugged, and through misadventure the rug was left off on a cold night, his health would be seriously imperilled. The horse was the best judge of when he wanted a drink. Forty pounds of chaff was a good daily ration for a horse. Some would undoubtedly eat more if given them, but over-fed horses were lazy. He recommended flowers of sulphur and lard for sore shoulders.

**EXPERIMENTAL PLOTS.**—The Hon. Secretary reported that four plots had been sown by Mr. Braithwaite. The first plot had no manure, the second 30lbs. 36 per cent. superphosphate per acre, the third 50lbs., and the fourth 80lbs. per acre.

**LIBRARY.**—It was decided to start a library with a bound volume of the *Journal* and a veterinary reference book.

#### MANTUNG.

June 4th.—Present: nine members and two visitors.

**SEEDING.**—Mr. E. Nobes read a paper. Seeding, he said, should be commenced about the middle of March. First, oats, preferably Algerian, should be broadcast on new land and ploughed in to a depth of 2in. or 3in. A good second crop could generally be harvested if the stubble were cultivated early in March, or directly after a good rain between late February and the middle of April. He would also broadcast wheat on new heavy timbered land and after a good burn, plough it in to a depth of 2in. or 3in., and then lightly harrow. The plough should be a twin with a seedbox attached. Super. was not necessary on rich land the first year it was cropped. Sand should be ploughed to a depth of 2½in. and drilled with about 50lbs. seed and 50lbs. super. The varieties of wheat suitable for this district were Dart's Imperial, Federation, Pioneer Purple, Silver Baart, and White Tuscan. Stubble should be well ploughed and drilled with about 30lbs. super. and 45lbs. to 50lbs. of seed. Every farmer should put in about 100 acres of fallow each year. In reply to questions, he said early wheats should be sown late and late wheats early. Deep drilling was best.

**MONARTO SOUTH** (Average annual rainfall. 14in. to 15in.).

July 4th.—Present: 27 members and two visitors.

**BLACKSMITH'S SHOP.**—Mr. H. Hein read a short paper on "The Blacksmith's Shop on the Farm." In a district like this, he said, where the farmer was some distance from the blacksmith, he could well make his own S hooks, eye bolts, &c. All that was necessary for this would be a small galvanized iron shed, an anvil not less than 1cwt. in weight, a strong vice, bellows, stocks and dies, several pairs of tongs, hammers, chisels, a drilling

machine, and a few bars of iron of different sizes. A few tools could be purchased each year until the farmer had a complete set. Members agreed. At first the farmer would be somewhat clumsy; but he would soon become used to the work and be able to do a good many small repairs. Not only would outlay on repairs be saved, but in many instances a great saving of time would be effected.

**PARILLA** (Average annual rainfall, 16in. to 17in.).

July 2nd.—Present: 11 members and three visitors.

**FARM HORSES FOR PARILLA DISTRICT.**—In a paper on this subject, Mr. C. Millstead said the farmer should select such horses as he considered suitable for his conditions. The Shire, a heavy, hairy-legged animal, compactly built, and very strong was suitable for drawing heavy loads, but too slow for farm work. The medium draught was generally a good worker. The Clydesdale was, perhaps, the most popular breed with farmers. It was strong and active, and would generally be found the most suitable animal in this district. The farmer was advised to breed from his best mares and the best horse of suitable type available. Mr. Roachock favored the medium draught. Mr. A. J. Stevens preferred an active horse with a fair amount of weight, and not too free, but a steady worker. Mr. J. Tee advised the medium draught for work in land that was not too stiff. For the plough the strongest horses should be used, and the light, quick walkers were best for the drill. Mr. A. Moyle favored the Clydesdale. Messrs. S. Gregory, J. J. Foale, E. J. Kerley, and H. G. Johnston preferred heavy animals. A vote as to the suitability of the different breeds for this district was then taken and resulted as follows:—Clydesdale, 8; Shire, 1; other breeds, 1.

**WAIKERIE** (Average annual rainfall, 8-89in.)

July 9th.—Present: five members and 15 visitors.

Addresses were delivered by Messrs. G. R. Laffer, M.P. (Chairman Advisory Board of Agriculture), S. McIntosh (Director of Irrigation), and G. G. Nicholls (Secretary Advisory Board). Mr. Laffer dealt mainly with the question of packing fruit for export. There was a good market for oranges, he said. Figs should do well, but the apple grown in this district seemed to lack flavor and was too thick in the skin. The Mylor type orchard should afford guidance to local growers. Mr. McIntosh referred to the growth of lucerne and cactus, samples of which were tabled. They had been grown at Berri outside the irrigation area, and were an indication of what might be done in the way of providing fodder for stock. Mr. Nicholls dealt with the general working of the Branch. Messrs. Odgers and Parks also spoke.

**WILKAWATT** (Average annual rainfall, 16in. to 17in.).

July 4th.—Present: 17 members and three visitors.

**WHEAT CULTIVATION.**—Mr. G. Oram read a paper on this subject. A more satisfactory germination of wheat would be secured, he said, where the farmer sowed good plump seed. The physical properties of the soil could be modified by cultivation. The wheat plant was partial to a firm, damp subsoil, and in a deep alluvial soil a good seedbed could be secured by fallowing to a depth of 4in. or 5in. and then cultivating and harrowing lightly in October and March. To allow the fallow to set down hard and then plough it back to a fair depth was not a satisfactory procedure. The tendency of crops to "go back" in the spring was, he thought, due to an improperly prepared seedbed. Plant food, to form the flowers and grain of the wheat, was carried in a solution from the roots to the head, hence a short-strawed wheat such as Federation should finish off better than the longer-strawed wheats, and should resist hot winds and drought. Mr. D. F. Bowman thought deep ploughing brought too much clay to the surface. He would fallow well, work the surface loosely, and allow it to remain. Mr. M. Neville agreed that a poor seedbed was the cause of crops failing late in the season. Several members said Federation was the best wheat they had grown.

**BERRI.**—July 8th.—Addresses were delivered by the Chairman of the Advisory Board (Mr. G. R. Laffer, M.P.), the Director of Irrigation (Mr. S. McIntosh), and the Secretary to the Advisory Board (Mr. Geo. G. Nicholls). Mr. Laffer dealt principally and ably with the fruit markets at home and abroad, touching upon co-operation in packing and grading and export of fruit, some varieties of pears and apples suitable for export, and expressed his pleasure at the work already accomplished at Berri. His address was much appreciated, as were also the remarks of Mr. Nicholls on Bureau work. Mr. McIntosh's assurance that the interests of the settlers were being safeguarded in every possible way also gave general satisfaction. An interesting and instructive evening came to a conclusion at 11 p.m.

**COOMANDOOK.**—Mr. P. C. Potter contributed a paper dealing with the relative advantages of farm and city life. The farm life, he said, was healthy, free, and there was a greater variety in the work, whilst in a large number of cases occupation in the city did not afford these advantages.

## SOUTH AND HILLS DISTRICT.

### CHERRY GARDENS (Average annual rainfall, 35·03in.).

July 7th.—Present: 13 members.

**FEEDING DUCKS.**—In a paper on this subject, Mr. C. Ricks said for the first few days, after ducklings were 48 hours old, they should be fed on bread crumbs, or crushed husked oats soaked in water or milk, separated or fresh, and mixed so that it would crumble nicely in the hands. After a week they could be given corn (good wheat was best) morning and night. The mid-day meal should consist of mixed bran and pollard, to which should be added every second day 1lb. of poultry meat meal for each 100 birds. This quantity should be increased to 2lbs. when the birds reached the age of six weeks. Greenfeed was necessary in abundance; the following being good for both ducks and fowls:—Maize, lucerne, mangolds, kale, refuse cabbage and turnips, and red and silver beet leaves. The plan he adopted was to run the greenstuff through the chaffcutter and mix it with the meal. In addition green feed should be available to the ducks at all times. Curdled milk was good for fattening. This was a cheap means of rearing marketable birds, and those he had raised last year were sold at prices ranging from 5s. to 8s. per pair. The live weights of two Muscovy ducks were 8lbs. 2ozs. and 7lbs. 10ozs. respectively. Mr. T. Jacobs, sen., advised substituting boiled rabbit for poultry meal. Mr. Ricks mentioned that some breeds of ducks, especially the Muscovy, did best, both for egg production and table use, with only sufficient water for drinking purposes.

### FOREST RANGE (Average annual rainfall, 35in. to 36in.).

July 2nd.—Present: seven members and one visitor.

**THINNING FRUIT.**—Mr. E. Green read a paper on this subject as follows:—“The practice of thinning fruits during the early stages of growth is one that merits a good deal more attention than it at present receives in this district. In many fruit-growing centres it is regarded as a most essential phase of successful fruit culture. My own experience of the process, though not a broad one, has been such as to convince me beyond all doubt that it could be employed with advantage to a very great extent in our own district. There are, I know, a large number of orchardists who maintain that trees (I am referring particularly to the apple), provided they are well cultivated, pruned, sprayed, and occasionally manured, require nothing more to ensure good crops of the best quality fruit. While the trees are young and vigorous, I admit that the aforementioned treatment is quite adequate, for, until they arrive at an age of, say, 12 or 15 years in a district such as ours there is little danger of the trees setting more fruit than they can mature in a satisfactory manner. As the trees become older, however, there is a strong tendency with many varieties to only crop on alternate seasons, and then so heavily that the trees are considerably over-burdened, and the result is that in many instances the fruit does not get a chance to develop to anything like its normal size. Frequently a large percentage of it is so small as to be of very little commercial value. These remarks apply particularly to such varieties as Winter Pearmain, London Pippin, Rokewood, Buncombe, Ridgeway. There are growers who say that the whole trouble is caused through allowing the trees to have too much fruit-bearing wood, and that it could be averted by judicious pruning. I am not prepared to agree with this, for, while severe pruning of such trees may have the effect of improving the quality of the fruit for the succeeding crop, the subsequent results do not often prove advantageous, as after receiving such treatment the trees usually produce an exuberance of wood growth but very little fruit for several years after. Then, too, if the variety so treated happens to be at all susceptible to ‘bitter pit’ the ravages of the disease are likely to be very much increased, owing to the abnormal flow of sap. It seems to be one of Nature’s laws that a balance shall exist between the root and branch growths of a tree. When large quantities of wood are suddenly removed that balance is seriously disturbed, and this is always detrimental, as most of us have discovered to our cost. For these reasons I would not, therefore, use the pruning saw too vigorously, but would allow the tree just a fair amount of wood, and if they appeared to be carrying too much fruit I would thin out until only such quantity remained as one would deem the trees capable of properly

developing. The process of thinning out should be performed in early December, although I do not think it would make much difference if done either a little earlier or a little later in the season, for it is not always convenient for an orchardist to carry out a work just at a fixed time. The thinning should be as even as possible, not allowing some branches to carry much more fruit than others. It is also advisable to reduce the clustering of fruit, and where there are groups of, say, five or six apples, it would be as well to leave only two or three. Apples, when grown in bunches, never present such a nice appearance as those not grown so close together and which are consequently more exposed to the sun's rays. A careful lookout should be kept for fruit showing signs of disease, and when such is detected it is, of course, policy to remove it. When *fusicladium* is at all prevalent, as unfortunately it too often is, pick off the infected fruit; the quality of that which remains is thereby much improved. With the uninitiated, when engaged in thinning there is always a feeling that too much fruit is being removed. It is very seldom, however, that that happens, for if one errs at all in judgment it is almost invariably on the side of leaving too much. It is often asserted that it will not pay to thin fruits because it entails too much labor. The fallacy of that statement is, however, easily exposed. The time required to treat a tree, say, carrying eight cases, would probably be about an hour. Suppose, for the sake of comparison, that as a result of the thinning out process the apples were increased in value by only 6d. per case, that would represent 4s. for the outlay of an hour's labor. The benefits of the system do not end just here either, for if it were put into extensive operation, the very large quantity of small and inferior fruit which is at present produced would be considerably reduced. That result would obviously be advantageous to all engaged in the industry, as the presence of large quantities of inferior fruit on the market always has a depressing effect, and prices, even for the best quality fruit, suffer in consequence. So far, I have only dealt with the system as it applies to apple culture. It can, however be employed with equally satisfactory results to most of the stone fruits, particularly the apricot, peach, and many of the varieties of Japanese plums. A much improved sample of fruit can always be obtained from these species when judicious thinning has been resorted to. With stone fruits the thinning out should be carried out earlier than for apples. November, I think, should be about the correct time." Mr. F. Green thought this practice would be found payable where the export trade was being catered for. When the fruit was in bunches it was difficult to pick the large apples without knocking off the immature fruit. He had thinned four Winter Pearmain trees and left two unthinned. The former produced a good sample of fruit, whilst that from the latter was useless. Mr. H. Schultze secured a 25 per cent. better crop of fruit from thinned London Pippin trees than those not so treated. Mr. E. Rowley thought judicious pruning better than thinning. Mr. McLaren agreed.

#### GUMERACHA (Average annual rainfall, 33 30in.).

June 9th.—Present: eight members.

**SOIL FERTILITY.**—Mr. J. B. Randell gave a very interesting address on the fertility of the soil and how to retain it. The subject was dealt with in a masterful manner and called forth criticism from all the members, who fully agreed that farmers, as a rule, should give the matter more serious attention, and see to it that they returned more manure to the soil to make up for that which was drawn from it by cropping and grazing.

#### KANMANTOO (Average annual rainfall, 17-90in.).

July 4th.—Present: 17 members and three visitors.

**SKINS.**—In a paper dealing with the preservation of skins, Mr. R. Talbot said the trotters should be left on sheepskins; they could be cut off when the skins were being packed. The skins should be put longways over a wire and tied down at both ends, or kept down with a small piece of wire, on both ends of which a small weight was affixed. They should not be dried in the sun, which would cause them to have a greasy appearance. Chaff or dirt would result in the value of the skins depreciating. They should be packed woolly side outwards and marketed as early as possible. Hides should be thoroughly salted, rolled, and sent to market promptly. Fox and rabbit skins would be spoiled if dried in the sun. The former should be pegged out squarely and left until quite dry, then brushed and combed to remove knots or spots of blood from the fur. On no account should they be dressed with saltpetre or alum if intended for market.

#### MEADOWS (Average annual rainfall, 35-52in.).

June 9th.—Present: 12 members.

**CARE OF FARM IMPLEMENTS.**—The hon. secretary (Mr. W. H. Bertram), in a short paper, gave the following hints in connection with the care of farm implements and

machinery :—"When an implement is constructed partly of wood, remove the wooden parts and give them either a coat of paint or of crude oil. The latter is one of the best wood preservatives known. Then store them compactly under a roof somewhere where there will be free circulation of air and protection from wind and rain. The metal or iron parts that are to be left out in the weather should receive careful attention. The working wearing parts should be protected by a heavy covering of hard cylinder oil, or of the best quality of wagon grease. Oil holes should be filled with corks or stoppers, and entrances to bearings protected. No part of the implement should be permitted to rest on the ground, but should be supported by planks or fence posts. On the non-wearing parts paint should be renewed. The unpainted parts should have a covering of cylinder oil; this will keep out air and moisture and prevent rust. When it comes time to use the implement again a little kerosine with a rubbing cloth will put it in condition for immediate use. Mr. S. Smith, speaking as a tradesman, said that farmers generally did not give nearly the attention they should to the woodwork of their implements and vehicles in preserving their durability by giving them a coat of oil or paint to protect them from the weather. There should always be a good coat of white lead underneath the paint. The majority of gloss paints would not last 12 months. Mr. T. B. Brooks used to paint his van every year with gloss paint, but he was inclined to think that there was more lead paint used in years past than at the present time.

#### MOUNT BARKER (Average annual rainfall, 30-93in.).

June 10th.—Present: 48 members and eight visitors.

**FRUIT-CULTURE.**—The Horticultural Instructor (Mr. Geo. Quinn) delivered an address. He recommended planting apples, pears, and plums for the main crop, and then peaches and apricots. The pears should be put on the low lying and wettest portion of the site, plums on the hillsides, and apples on the slopes and hilltops. Late summer and early autumn were the best times to plant. The best varieties were—Apples, Jonathan, Rome Beauty, Worcestershire Pearmain, Dumelow's Seedling, Five Crown or London Pippin, Dunn's Seedling, Cleopatra, Delicious, Stayman Winesap; pears, Glou Morceau (on quince stocks), Beurre Bosc, Diel, Doyenne, Du Comice, Josephine de Malines, Madam Cole, Packham's Triumph, and William's Bon Chretien (Duchess); plums, Prune d'Argen, Splendour, Felleberg, Jefferson, Golden Drop, Green Gage; apricots, Moorpark; peaches, High's Canada, Hale's Early, Peregrine, Louis Groquet, Mountain Rose, Early Crawford, and Elberta. A number of questions were asked and replied to by the lecturer.

#### MOUNT BARKER (Average annual rainfall, 30-93in.).

July 10th.—Present: 40 members and two visitors.

**FARM MANAGEMENT.**—Mr. F. Simper read a paper on this subject. The following is extracted therefrom :—"The arrangements on a farm should be well thought out. First of all it will be necessary to make sure that the property is well fenced. Boundaries should be sheep-proof and for preference wire-netted; 4ft., 1½ in. gauge netting should be used. This will keep rabbits out and prevent sheep from straying. A barbed wire well secured to the tops of the posts will prevent large stock pushing the fences out of shape. All farm buildings should be erected as conveniently as possible. Select a spot that is easy of access, so that a good road out is obtained. The poorer part of the land will be best suited for this purpose, because the better parts will be required for cultivation purposes. The dwelling-house, and also all out-buildings, will have to be built according to the capital available; but it is well to bear in mind that it costs very little more to roof a high building than a low one covering the same area. The next thing to do will be to divide the holding into suitable paddocks. If good running water is available a great deal of labor and expense may be saved in the watering of stock by erecting the fences in positions so that water can be approached as easily as possible. All trees, with the exception of a few for shade in the summer, should be grubbed below plough depth on cultivation paddocks. No stumps should be allowed to remain, much time and breaking of machinery can thus be saved. Furze hedges, briars, thistles, and in fact all noxious weeds should be eradicated from all parts of the property. Fortunately, most of our cultivation land in this district has been partly cleared, therefore a good strong old-fashioned plough can be utilised for the hilly land. The double-furrow ploughs, with a strong beam and long handles, is, to my idea, the most suitable for all-round work in this district; although, when a paddock has been deeply turned over for a crop of peas or potatoes, the following year it may be merely stirred with an ordinary cultivator and then drilled in, that is, providing the land is free from wild oats and sorrel. This will often grow a better crop of wheat or oats than if again ploughed deep. If possible the light soils should be ploughed early. Wheat or oats will, on this kind of land, do best

if up and growing before the severest part of the winter sets in ; heavy soils will do later.

*Peas.*—With the exception of peas, and perhaps barley, all cereals should be sown by the end of June. Before the introduction of seed drills in this district peas were sown much earlier than now. By using artificial manures and drilling-in the seed the peas are forced on a great deal more quickly than formerly, and it is now a question as to whether they are likely to escape the late frosts or catch the first hot winds. Peas will, in the near future, receive more attention on the farms in this district. We can grow and harvest crops of this kind second to those of no other part of the State. The Lower North and drier district farmers are rapidly seizing the idea of growing peas instead of leaving their fallows bare, and then feeding them off with sheep. Besides that there is an increased demand from other parts of the world for this food. Fruitgrowers sow peas between the trees, and these are ploughed in for green manure. The seed must be had somewhere, and this district should be able to supply. The greatest drawback which confronts us at present is the harvesting of the crop. Many new improvements have been patented. The attachment to the ordinary mower for cutting the peas is very good. The pea rake is used in some districts ; but something is still wanting to prevent the blowing about in the paddocks and the heavy work of forking the straw. A crop of peas if fed off will fatten 15 sheep to the acre. If an increase of, say, 3s. 6d. a sheep, is made on the buying price of stores, a return of 52s. 6d. an acre is secured for the crop. Supposing the crop yielded 30 bush. to the acre, at 3s. 6d. per bushel it would be worth £5 5s. an acre. Allowing £1 10s. per acre for harvesting the net return would show as £3 15s., or £1 2s. 6d. better than for sheep, and sheep could still be put on the land to eat the rubbish and peas lost in handling. If we can get a machine to cut and thresh this crop in the one operation a saving of at least another £1 per acre could be effected.

*Hay.*—This district is not one that is looked upon as a wheat district. Most crops are cut for hay. A paddock that will grow, say, 2½ tons of good hay to the acre, will pay better by growing hay than by being left out for feed or carrying a grain crop. Bad weather usually damages a heavy crop. Late varieties of wheat are best here, as the chaff from these is better. The Tuscan wheat is still thought most of. Oats and wheat mixed make good hay. Algerian oats sown with Tuscan wheat are the best, because they are ready to cut about the same time. For early sowing on dry land it is not wise to pickle the grain ; but for late sowing, and especially if intended to be left for seed, it is necessary to do so. My experience is that a pickle of 11b. of bluestone in 10galls. of water is strong enough. The fertility of the soil should be kept up to its best. Well-ploughed land need only be harrowed once before being drilled, and if possible a soil grinder should be dragged over it in the opposite direction to that in which it is drilled. Any manure can be applied with advantage, but where we have an average rainfall of over 30in. bonedust is to my mind best. Harrowing crops after they are up may do good in some seasons if the land is dry at the time. All crops should be rolled if only harrowed after the drill. Crops that are sown early usually give the best returns for hay. They are, as a rule, thicker and higher, and are not so likely to be affected with rust or smut.

*Stock, &c.*—The most suitable type of horse for all-round farm work in this district is an active medium-weight Clydesdale. The heavier type may be better for ploughing stiff soils, but for the greater part of the work, such as harrowing, drilling, cutting the crops, trolly work, &c., the more active sorts are to be recommended. Feed the horses well, likewise all farm stock. If an animal will not pay for its feed get rid of it. Cows and sheep are required to feed off the paddocks that are not under crop. Breeding horses for use on the holding has paid for a number of years. Pigs and poultry deserve their share of attention. A paddock which has been frequently cropped will not grow much grass the first year when left out, so I advise sowing it with barley or some other early feed-producing cereal. Put a cultivator over it and then a soil grinder to level it, and with early rains it will provide an abundance of feed for stock during the winter. If a very fertile gully is available attention can be given to growing onions, potatoes, lucerne, mangolds, turnips, maize, &c. In fact it has been proved that potatoes will grow almost anywhere in this district in favorable seasons. Farmyard manure can be made good use of by way of intense culture. Fruit-growing may also be added, but owing to the increased trouble with birds and other pests, this line will eventually be left to the gardener. Irrigation will be thought more of by the farmers in the future. Those that can get a supply of water, which costs less than 6d. per thousand gallons, will make it pay."

MOUNT COMPASS (Average annual rainfall, —in.)

June 25th.—Present : 11 members and five visitors.

This constituted the inaugural meeting of the Branch. The Secretary to the Advisory Board addressed the gathering on the subject of the general organisation and management

of the institution. Mr. M. Jacobs expressed his gratification at the fact that the service of departmental experts were available to producers, and felt sure that the latter would greatly profit thereby. He referred to the rapid development of gardening in the Mount Compass and Nangkita districts. In the early stages the struggle had been hard, but with the sympathetic feeling which existed between the officers of the department and the producers, an evidence of which was the visits of the former to the district and the experimental plots being conducted in the locality, the way was becoming much easier. Messrs. Peters and McEwan expressed their appreciation of the work accomplished by the Bureau.

#### URAILDA AND SUMMERTOWN (Average annual rainfall, 44-35in.).

July 6th.—Present : nine members.

**FRUIT AND VEGETABLE CULTURE IN THE HILLS.**—In a paper dealing with some of the disadvantages of cultivating fruit and vegetables in the hills, Mr. R. L. Cobbleidick said the value of land in this district was generally overestimated. Areas in their natural state, for instance, valued at £10 per acre cost from £20 to £30 per acre to clear. Cleared land cost up to £100 per acre. Most of the best soil was in the gullies, which involved heavy work. Fruit and vegetable growers also had to contend with numerous pests, and the labor in preparing the crops for market was considerable. Many other difficulties peculiar to the nature of the district were enumerated by the writer of the paper.

**TOMATO-GROWING.**—This formed the subject of a paper by Mr. J. M. Bonython. He considered that with the high prices ruling for tomatoes this crop could, with trellising, be profitably cultivated in this district. Seed should be planted the first week in August in 3in. or 4in. of sand over a foot of hot stable manure, and protected from frost and rough weather with a wire netting frame supporting a calico cover. For convenience the bed should be situated close to the homestead. When the plants were 1in. high they should be placed 1in. apart in rows 6in. apart, which would encourage the development of bushy roots. After the danger of frosts had passed, and the plants had reached a height of 8in. or 9in., they should be put in rows 4ft. apart, with 3ft. between the plants in the rows, in land that had previously been well-ploughed and harrowed. A wire 3½ft. above the ground should be run through a line of stakes set beside each plant. A small quantity of bonedust should be given each plant, and as it grew it should be pruned and trained up to the wire. Cultivation should consist of using the Planet hoe with a horse and hand-hoeing the strip around the tomatoes. Water could be run down between the rows, one or two waterings only being necessary. Mr. R. N. Cobbleidick had grown this crop and advised trellising. Messrs. Hart, Collett, and other members agreed.

**LONGWOOD, July 4th.**—The meeting was held at the homestead of Mr. E. H. Glyde. An enjoyable and profitable afternoon was spent inspecting the property. Members agreed that pig-raising was becoming a prominent industry in the hills. The paper read by Mr. P. T. Bowker, of the Laura Branch (see page 1186, June issue), was read and commented on as being of considerable value.

**MEADOWS, May 5th.—FEEDING DAIRY COWS.**—A discussion was initiated by Mr. Jas. Morris on rations for feeding dairy cows in southern districts, as supplied to him by Mr. Suter (Dairy Expert). The Chairman (Mr. Geo. Ellis) considered there was more nutriment in pea straw than in any other. Mr. Brooks was of opinion that a lot of valuable pea straw was wasted in this district. Mr. Phillips thought it a good plan to chaff up greenfeed and pea straw together, but care must be taken to harvest the pea straw in a sound and clean condition.

**MENINGIE, June 11th.**—Mr. Wright contributed a paper on "The Outlook of Agriculture." A general discussion followed.

**MOUNT PLEASANT.—HOMESTEAD MEETING.**—The members met at the homestead of Mr. H. H. Giles and inspected the garden, poultry yards, &c. It was reported that stock in the district were doing particularly well for this time of the year. Dry conditions had retarded cropping, but early-sown crops were looking well.

**STRATHALBYN, July 6th.**—The annual meeting, which took the nature of a social gathering, was attended by about 85 ladies and gentlemen. The following toast list was honored:—"The King," "Agricultural and Pastoral Industries," "Kindred Societies," "Town and Trade of Strathalbyn," "The Ladies," and "The Press."

## SOUTH-EAST DISTRICT.

GLENCOE (Average annual rainfall, 33.84in.).

April 6th.—Present : nine members.

**IMPROVING THE INFERIOR LAND.**—Mr. T. F. Gratiwick dealt with this subject in a paper. He said—“The problem of dealing with our poorer lands is one that will doubtless receive increasing attention as the years go by. During the past 10 years, through the medium of Algerian oats and Snowflake potatoes, we have reclaimed a good deal of the ferny second-class land, which was at one time regarded of very little value from either a grazing or agricultural point of view, and have turned it into good, sound grazing country. During the next decade probably greater developments, along these lines, will take place, because as the better class country, much of which is already closely settled, becomes dearer, the cheaper lands will receive more attention, and the high prices ruling for wool and meat will tend to encourage development in this direction. Originally much of this land had a considerable grazing value, and we hear old residents talk about the fat bullocks and Indian remounts that used to come off a particular strip of country, where to-day, owing to the depredations of rabbits, a fat bullock is unheard of. As this is a case in which the saying ‘what has been can be again’ holds good, it behoves us to consider how we may bring about this very desirable result. The poorer country comprises a variety of soils, the poorest no doubt being the white sand on which the genuine stringybark grows, and I am of the opinion that nature’s arrangement, which planted our most valuable timber on our poorest land, cannot be improved upon, and this class of country is best conserved as forest reserves, whether Crown land or freehold. Here the *Pinus insignis* or Remarkable Pine also flourishes, and I am told that a pine plantation 20 years old is worth £100 per acre, provided it escapes destruction by fire. Before we proceed to improve the grazing capacity of our rough block we must see that there is a good rabbit-proof fence all round it, taking care that at least 18in. of netting is countersunk in the ground where the line runs through warrens. The class of country coming next to the stringybarks has usually at one time been covered with messmate and a sort of peppermint gum. The soil is a light sand, with red banks at intervals, and covered with bracken fern and very few yaccas. In its natural state it is of little value as a grazing proposition, but with a little cultivation is capable of considerable improvement. The clearing must necessarily be of a rough and ready style, such as burning up fallen timber and chopping or burning off such stumps as are easily dealt with. The implement *par excellence* for breaking up this country is the disc plough, either stump-jump or set, but preferably the former. If you are going to make a real good job use the disc harrows over a couple of times before drilling, and drill in a sample of Algerian oats that has plenty of spear grass amongst it—the more spear grass the better. A little Italian clover mixed with the seed generally does pretty well, and being a nitrogen collector no doubt enriches the soil a little. However, as this is an annual it usually dies out after two or three years, probably through the stock eating most of the seed. I would not advise saving the crop for harvesting, but if a little is wanted, cut or strip out the best patches and turn the stock on the remainder. As regards manuring, there seems to be an opinion amongst practical farmers that about 40lbs. of mineral super. gives the most profitable return. I have seen this class of country sown in March with spear grass from the oat mills, carrying stud ewes and lambs in July, and the sheep doing better than they did on land worth £20 per acre. Should there be a patch or two of fresh water ti-tree on low-lying ground or along a watercourse—according to a Victorian practice, which has only been in vogue a few years and is highly spoken of—the cheapest method of converting such land into grazing country is to slash down the ti-tree, preferably in the autumn, and allow it to lie until well on in the following summer, when a fire is put through it, and what is commonly known as Californian trefoil is sown broadcast in the ashes while they are still warm. This is a very necessary part of the operation, as if the ashes are not warm enough to heat the waxy covering of the seed a poor germination will result. The following spring there will be a luxuriant growth of green stuff knee high, which, according to analysis, at one stage of its growth possesses a feeding value almost equal to lucerne, though, from what I have seen of it, stock touch it very little until it is ripe, after which they keep at it until they have eaten up every straw. If there is a strong growth of ti-tree shoots, it is advised to stock very lightly and burn during the following summer, on the same principle as mallee farmers, who like a good stubble to burn mallee shoots. There are also various clovers which flourish on ti-tree land, notably the strawberry and beech forest or birdsfoot clover. Both of these yield a fair amount of good herbage and have the special advantage that, although they may be under water for several months during the winter, when the spring comes and the waters subside, they come up fresh. On some swamps, even in the stringybark country,

during a favorable season, something may be done in the way of catch crops. Ploughed and sown with rape and mustard a good growth is frequently obtained, which provides the best of grazing at a period of the year when feed is generally not too plentiful. Of course, the length of time during which one can graze it depends entirely on how soon the water comes down. But before any of these desirable results can be brought to pass the rabbits must be cleared out. There are various other classes of country, I might mention, such as the Woakwine Range, which under various names runs from a few miles this side of Kingston into Victoria, and comprises many thousands of acres, much of which, at one time, was very useful grazing land. The formation is wholly limestone or sandstone, the presence of which, experts tell us, is a sure indication of oil. Little can be done with this class of country beyond keeping down the rabbits, burning off fallen timber, and providing salt licks. There are also the flinty flats which are a feature of the country between Coola, Mount Schanck, and the coast, the continuation of which into the sea provides the pebbles for the Cape Banks Flint Company. These flats, although almost as stony as the metal road, possess wonderful recuperative powers once they are cleared of rabbits, the best of them carrying as high as two sheep to the acre. Although there is a great deal to be said about the best means of improving our poorer lands, the first principles can be expressed in a very few words—keep down the rabbits, and do not overstock. Provide plenty of good water, have a salt lick in the paddock, and, if possible, plough up 50 or 100 acres and sow with oats and spear grass every year." Mr. J. Dow thought that the stringybark country would be eminently suitable for fruit growing. Mr. J. Holloway disagreed. He believed that the lower country on the fringe of the ranges was the best fruit growing country available. Mr. H. A. Cameron thought the quality of fruit from that class of country would be excellent, but that the preparation of the soil would be costly. Mr. G. E. Copping mentioned that the Government were taking the Murray water on to the higher levels, and settlers on the reclaimed areas were using this land for fruit-growing. He also mentioned that some years ago in the Lucindale district they had let 200 acres of rough country covered with yacobs to be cleared by contract; 100 acres had been cropped since and yielded up to 20 bush. of wheat and 3 tons of hay per acre, and the land would now carry a sheep to the acre.

#### GLENCOE (Average annual rainfall, 33.84in.).

May 11th.—Present: six members.

**FRUIT GROWING.**—Mr. J. L. Halliday gave an address on fruit growing, with special reference to varieties of apples suitable for this district, and methods of pruning. He considered that the Cleopatra was not suitable for this district; but said that possibly various apples would do better if worked on different stocks. Trees should produce an even crop of fruit each year, otherwise they were not profitable. They should always be kept low, as thereby hot winds had not the same disastrous effects, also picking was facilitated. The English Quarantine was a good early apple for fertilisation purposes. It was well to mix the varieties in the orchard to get an even fertilisation. Mr. Halliday always pruned twice, going over the trees roughly in the first instance, and then pruning more carefully and thoroughly later on. He removed old wood each year and promoted main stems of new wood, as apples grown on old wood were liable to crack. Mr. T. F. Gratwick said that Rome Beauty did splendidly in this district. Mr. P. Clifford said that in pruning old wood out of pear trees very often several shoots grew out, and asked what should be done. Mr. Halliday advised cutting all but one, which should be pinched back.

#### KEITH (Average annual rainfall, 19.20in.).

June 6th.—Present: 11 members.

**SICKNESS ON THE FARM.**—This subject was dealt with in a paper by Mr. A. V. Thompson. Owing to the difficulty in obtaining professional advice and medicine in the district, he said, it was advisable for every farmer to keep a stock of homœopathic remedies, together with a veterinary homœopathic pocket manual, on hand. A few of the more important drugs which he had found of use were aconite, nux vomica, arsenicum, cantharides, ammonium causticum, mercurius, and sulphur. He related his experiences with different ailments which he had successfully treated and emphasised the importance of thoroughness in dealing with matters of this nature.

June 11th.—Present: 10 members and one visitor.

**PICKLING WHEAT.**—Mr. C. H. Scholz read a paper on this subject. He had tried many methods of pickling, but the one he adopted last year he thought was the most thorough. The plant consisted of a large barrel cut in halves. One half was let into the ground and the other placed so that the bottom of it overlapped the top edge of the

underneath vat. The top cask or vat was tapped at the bottom and used for draining off the solution, which consisted of 2lbs. of bluestone to 10galls. of water, and was placed in the top vat. The wheat was poured in and not steeped in a bag. By this method all light and useless seed and chaff came to the surface and was skimmed off. After stirring well, the plug or tap was turned, and the solution drained into the bottom vat. A piece of gauze was placed over the whole to prevent any wheat running through with the solution. Unless the wheat contained much drake it was not necessary to winnow or grade, as all the waste was brought to the surface in the solution and skimmed off. The wheat should be sown as soon after pickling as possible. This year his pickled wheat had germinated as early as that sown dry, which he thought was due to its having been sown as soon as it was dry enough for the drill. Mr. Hahn thought the solution recommended (2lbs. bluestone to 10galls. water) was much too strong and would seriously interfere with germination. The wheat should be properly graded before being pickled. Mr. Schinckel thought that 1lb. to 10galls. was quite strong enough. Mr. Alcock had tested pickling with from 1 per cent. to 3 per cent., and the latter showed a very low rate of germination.

July 2nd.—Present : 12 members.

THE INTERNAL COMBUSTION ENGINE ON THE FARM.—This subject was ably dealt with in a paper by Mr. S. Shepherd. Dealing with the historical side of the internal combustion engine, he mentioned that it was spoken of as far back as in 1678, but as the steam engine received so much attention it was neglected largely until 1862, when the law of the four cycle was discovered. This was in 1876 practically applied and patented by a German—Otto. The paper continued—“When the Otto patent became public property in 1890 most of the two-cycle engines were abandoned and the more successful and popular Otto type adopted. However, we find quite a number of these two-cycle engines being sold to-day, and in some cases working with a fair measure of success; but the general construction of quite a number that I have inspected does not lead one to think that they will displace the well-designed Otto engines as manufactured by the leading British makers. Weight for weight they will no doubt develop more power than the Otto type on account of the extra number of impulses; but weight is not always an objectionable feature in a farm engine, and further, although they dispense with valves, much depends on the condition of the rings for successful working. Scientifically they are lacking, and I should not advise the purchase of one above, say, 6 B.H.P. unless built on the Diesel pattern. In purchasing an engine there are many points to consider. Power is not everything; price is not all; and the remembrance of quality and faithful service remains long after the price is forgotten. You will no doubt be canvassed by the representative of the gigantic ‘I am’ concern, who will be pleased to inform you that his four is quite equal to all the other fellows’ six, and that his petrol engine will work at less cost per B.H.P. than an oil engine. It no doubt sounds nice to the prospective buyer, and having told the tale so often the seller really believes the same to be true. Now look a little further. Take an engine of stated dimensions designed to develop 6 B.H.P. at a piston speed of 600ft. per minute, that is six times 33,000ft. pounds. Now, suppose for argument sake we speed the same engine up to 900ft. per minute, which our friend forgets to tell you that he does; what is the result? ‘Twenty years’ life against 30 at the slower speed. Of course you will have noticed that all internal combustion engines have high piston speeds, and speed, up to a certain limit, is where their great thermal efficiency exists, for the main conditions of working are maximum volume of cylinder to minimum of surface; highest practical possible piston speed; maximum expansion; maximum pressure at the beginning of the stroke. Now, if you follow this closely you will observe that the cylinder of the leading engines is designed with the object of avoiding objectionable orifices and ports leading to valves, which should be vertical; and, seeing that 50 per cent. of the heat of the fuel is absorbed by the jacket water, it is evident that the less time allowance the less will be the absorption of heat by the jacket water. The maximum explosion force is three and a half times the compression, therefore high compression spells economy; but there is a limit, which is about reached in the ordinary oil engine, and the bulk of them does not exceed a thermal efficiency of 18 per cent., which is twice as good as the ordinary steam engine. There have been many attempts to raise the compression, but spontaneous combustion takes place within the cylinder, and the only successful method is embodied in the Diesel engine of German invention. The compression equals 50 atmospheres, and the oil is injected after the compression is completed, avoiding all pre-ignition tendencies. The primary conception of the internal combustion engine was associated with the use of volatile oils, but before the difficult problem was satisfactorily solved the simplest gas engine became firmly

established, and not until 1876 can we consider the oil engine to have had a separate practical existence. One is often asked which is the correct engine for the farmer to buy. To this question I would ask, what is the nature of the work expected to do? If for irrigating and continuance running, then the oil engine will undoubtedly most ably fill the bill; for, although the calorific value of kerosene and petrol are closely associated, the cost of petrol against the heavier oil is about double. In the oil engine you have high compression with automatic ignition. Against this in the petrol engine you have the more accurate magneto electric ignition but lower compression, so that either leave little to be desired; but if your engine is required for chaff-cutting, say about 100 tons per annum, you will find the petrol engine much handier; but speaking generally, they have not the life of an oil engine, except perhaps a few that are modified gas engines put up by several of the leading British makers. I should always give preference to the horizontal type for farm use, being much handier to get at, more correctly balanced, and the crank does not carry the dead weight of the piston as in the vertical type. The compensating crank balance on the fly wheel is crude, tending to oscillation. In the horizontal type the crank and half the connecting rod require balancing, therefore the only correct balance is on the crank. The governors should be gear driven, avoiding belts, as belt failure may mean disaster, and as there are several different satisfactory methods I shall not attempt to describe them. In purchasing a steam engine one carefully asks the size of the cylinder, stroke, speed, pressure, &c., and from the data given can easily ascertain the power; but with an oil engine this is not so, as the different makers adopt different measurements. Therefore it is nice to have supplied an indicator diagram or a brake-test certificate, which is the only reliable guarantee as to power, as two engines may indicate the same. One may have a mechanical efficiency of 80 per cent. against the other 75 per cent., that is a loss of an extra 5 per cent. in engine friction, and as an indicator denotes the cylinder pressure it does not account for frictional loss. It needs but little arithmetical knowledge to make a brake test. The appliance consists of a strap, a spring balance, a few weights, and a speed recorder; but if you purchase from a well-established maker there is little to worry about in regard to power. The same applies to your future duplicate requirements. Personally I prefer maximum dimensions and large bearing surfaces combined with high thermal efficiency to maximum of power over that which you contract to buy, for most farmers will increase the load regardless of the engine's ability to withstand the strain, forgetting that it is cheaper for a maker to supply power in excess than it is to provide for a few extra years of service. Therefore, in purchasing an engine, buy a horse power or two extra, and do not depend on the maker throwing it in. I shall not attempt to describe the thousand and one minor details that go to make up an engine, but there are one or two that certainly require investigation. The crank should be made of the best steel procurable, as the severe stresses that it undergoes calls for a large margin of strength being allowed. Unlike a steam engine the cylinder pressure falls very rapidly, hence the maximum load exceeds that of a steam engine, and I generally notice that the crank shaft dimensions may be accepted as a reliable indication of a maker's integrity. Doubtless you have noticed one fly wheel on some engines and two on others. The man selling one wheel tells you that two are not needed; the man selling two wheels tells you that his is the best, and possibly they are both right. The latter's style and type of engine may not run within a speed variation of  $7\frac{1}{2}$  per cent. with one wheel, while 3 per cent. is within its reach with two wheels, and this is necessary for lighting purposes; but the mechanical efficiency of the engine is somewhat reduced, hence the need for using the lightest possible fly wheel, as the main bearing pressures are affected by the weight of the wheels and the thrust upon the crank, which combined should not exceed 100lbs. per square inch on the bearings. For this reason the wheels should be of large diameter, as the required weight varies inversely as the square of the diameter. If too large a wheel is used the centrifugal action may render it dangerous, and the rim speed should not exceed 100ft. per second. I have repeatedly noticed engines built with light frail cranks and main bearings to correspond, then two wheels are undoubtedly needed; but if the crank dimensions are there with ample bearing of surface there is nothing wanting with using one wheel, as the method of governing has also a large influence on acceleration. Therefore listen only to those that have proved their worth and acted as pioneers and are recognised as having an intimate acquaintance with the practical side of the subject."

MOUNT GAMBIER (Average annual rainfall, 32.00in.).

June 13th.—Present: 13 members.

SCAB IN POTATOES.—In response to an inquiry from another Branch with regard to scab in potatoes, Mr. R. Fowler stated that it had been found that scabby seed produced scabby potatoes as a rule, but on the other hand clean seed might produce scabby tubers.

but to a less degree. Mr. R. Smith had secured clean crops from scabby seed; a richly manured patch practically always yielded an affected crop. Mr. A. A. Kilsby said that if scabby potatoes were planted on swamp ground the crop would be clean, but if planted on rich ground it would be diseased. Mr. A. A. Sassanowsky found that the same potato might be affected with both scab and blister.

**AZOTURIA IN HORSES.**—Mr. Jas. Keegan read a paper in which he described the symptoms of azoturia in horses, which, he said, was generally due to excessive work after a period of idleness, during which the animal has been given liberal supplies of corn. The disease would not prove fatal if the driver gave the horse a spell immediately it became unduly excited. A lengthy discussion followed, in which Messrs. D. McGillivray, H. G. Wheeler, A. A. Kilsby, and A. A. Sassanowsky debated the nature of the disease and the efficacy of different remedies.

#### NARACOORTE (Average annual rainfall, 22.60in.)

June 13th.—Present: 14 members.

**RIVALRY AMONG AGRICULTURISTS.**—The paper on this subject, read by Mr. S. H. Schinckel at the May meeting (see p. 1231, June issue) was discussed at length by members. Mr. Rogers said healthy rivalry was always productive of good, and for this reason he favored agricultural shows. Mr. Bray thought competition stimulated improvement. Mr. W. H. Smith mentioned the benefit of homestead meetings in this connection.

**PLOUGHING-IN SEED.**—Mr. Loller had ploughed in seed to a depth of 3in., and compared with drilling, the results were satisfactory. Care should be taken to see that the soil was broken down properly and no large air spaces were left when this was practised. Mr. Bray mentioned an instance where medium results had been secured from land sown before being ploughed. Better results would have been secured, he thought, if it had been drilled in with manure.

**THISTLES ON FALLOW.**—Mr. Kelly reported that he had experienced considerable trouble with a variegated thistle on fallow. He had used the disc cultivator early in the year but later the land became too sticky. Mr. Loller recommended deep ploughing and cutting.

**EXHIBITS.**—Mr. Loller exhibited a fine sample of rye for greenfeed. It had been sown about the middle of March, and was about 3ft. in length. He also distributed among members some very fine apples grown in his orchard. The Chairman (Mr. L. Wright) handed to members plants of the Chinese cabbage, which was a good stock fodder, and was also used by some as a vegetable.

#### PENOLA (Average annual rainfall, 26.78in.)

July 4th.—Present: nine members.

**AGRICULTURAL EXPERIMENT.**—The Hon. Secretary (Mr. S. Ockley) read the following paper:—"The demand of the present day is progress, and agriculturists must not delay. Although the older order may shake their heads at the word 'theory,' yet science, as applied to agriculture, speaks for itself as being practical. Science and theory are immovable facts, the barriers requiring to be broken down being the fitful forces of nature, to do which requires keen observation, unlimited patience, and perseverance. Hence, the need for experiment. What constitutes the richness of the material world? If one found millions of sovereigns and distributed them to all, the world would not be one whit better off; it would only mean that there would be more money to buy the necessities of life, which means that money would have less value or, in other words, things would be dearer. But if, through advanced agricultural operations and the application of proved science or improved machinery, the amount of production of clothing, material, and food was increased, and that with the same, or less, amount of labor than formerly, then indeed would the world be richer. Consequently, it appears that the furtherance of such an end by means of experimenting should be a national work. However, there are certain experiments that can be carried out on a farm, and not interfere too much with seasonal occupations, such as applications of different kinds and quantities of fertilisers, and the advantages of different kinds and quantities of seed. But there are others that require special improvements and much time, and which are beyond the ordinary farmer's abilities to carry out. There is nothing like actual demonstration of improved methods to convince farmers, and this is one of the greatest arguments in favor of experiments being undertaken in every district. No man is content to earn £100 from a piece of land when it can be plainly shown that by the adoption of other methods he can reap £200. Which is the best direction in which this district can conduct plots? The main products of Penola may be enumerated as wool, oats, barley, fruit, wheat, and timber, with barely enough mutton and beef to supply its own wants and not enough potatoes and onions. By far the greater area is pasture, so that if a method can be shown whereby the carrying

capacity can be increased it would be a boon to the district. Of course, such methods as rabbit extermination, ringing, and clearing are beyond the experimental stage. The point is whether under present economic conditions it will pay to go farther than this. The manuring of grass lands has been conducted systematically in various centres, and has been found to pay when used for the production of mutton or milk; it is a question of doubt whether it would pay for the increased quantity of wool produced. An experiment to determine the result would need an experimental sheep farm and much care. I venture to state that it would pay to manure grass land on which it was intended to lamb down ewes. The majority of pasture land in the district lacks variety in the feed, the clover family being almost non-existent, mainly through the need of phosphates; the ordinary and less nutritive grass has sole control, because apparently it needs less phosphoric acid. This grass may produce a good even wool through its consistent growth all the year round, but it will make milk, or fatten, only when in seed. One hundred-weight of super. per acre would cost 6s. per acre, broadcast upon the ground. Would the added value (if any) of the wool of the ewe and the lamb and the added size of the latter pay for the application? It is an experiment which would interest by far the larger number of landholders, and one which I would like to see put to a thorough test. A fairly heavy implement, more or less like a harrow, but made so as not to pick up rubbish and which would loosen the soil about an inch, would be a payable implement on light grass land. Every year I make it a practice of collecting all the spear grass, geranium, and burr clover seed that is allowed to ripen in parts of the garden, and distribute it in the paddocks. Of course it is labor in vain if the rabbits are allowed possession. The three grasses mentioned grow well in the district if allowed, and there is no need to go to great expense buying seed, if a small convenient paddock be heavily dressed with farm-yard manure in which to grow these seeds. At Roseworthy, in the Grainger experimental blocks, to test the relative value of light and heavy dressings of super. on wheat, the application of 1cwt. of super. an acre has averaged 20lbs. of wheat above that to which 2cwt. was applied. Yet there is no greater advocate for a 2-cwt. dressing than Professor Perkins, who says that the returns from sheep more than make up the extra cost of super., i.e., the sheep return more than the 5s. for the super. and 1s. for the loss of 20lbs. of wheat, which comes to 6s. per acre. One would expect greater returns from the application of 1cwt. super. by applying it on to the grass in the following year instead of 12 months before it was wanted, and as a heavier rainfall allows greater carrying capacity, such a practice should be more valuable here. With regard to cultivation, it seems that in more advanced agricultural centres, where the rainfall approaches 30in. per annum, stock husbandry is the principal activity and wheat but secondary. Great Britain and New Zealand cannot make wheat growing pay with their 33bush. average. Our aim should be to make the most of our 27in. rainfall, which is quite sufficient to ensure two crops a year. What seems needed is to find the most suitable rotation for the district. It is the following of their laid-down rotation laws which has ensured the consistent success of the Wimmera and mid-northern wheatgrowers. Since the advent of multiple furrow, S.J. ploughs, drills and supers., land has come under cultivation which hitherto it was impossible to payably cultivate; consequently under the different conditions various problems occur. Much of the ground referred to is not so poor as it is considered, but suffers from its condition, because if a comparatively dry winter is experienced high yields are obtained, whereas a heavy glut of rain during the winter has such an effect that the yield is reduced by about one-half that of a dry year. How to overcome this is one of the problems that remains to be solved."

**LUCINDALE, July 25th.**—Members took the opportunity of presenting Colonel Feuerherdt with a life membership certificate in recognition of the service he had rendered this Branch. For 14 years he had occupied the position of Chairman.

**MILLICENT, July 14th.**—Mr. Holzgrefe made a further appeal for the establishment of a model farm in the South-East. The question was discussed by members.

**NARACOORTE, July 11th.**—An interesting social gathering for the purpose of presenting life membership certificates and doing honor to Messrs. S. H. Schinckel and D. Caldwell, was held in the Commercial Hotel. The chair was occupied by the President (Mr. L. Wright). The toast, "The Agricultural Bureau," was aptly proposed by Mr J. M. Wray and responded to by the Chairman, at whose instance the toast of the "Guests" was also honored. The Hon. Secretary (Mr. W. H. Smith), Messrs. W. E. Rogers, Holmes, Wray, and Loller supported and made eulogistic reference to the work of Messrs. Schinckel and Caldwell in the interests of the Bureau and agriculture generally. Framed certificates of life membership were presented by the Chairman to these gentlemen, who suitably responded.

T. PASCOE,

*Minister of Agriculture.*

**Four-Horned Sheep in Scotland.**

Some early references to four-horned sheep in Scotland have been unearthed by Dr. James Ritchie, of the Royal Scottish Museum, says the *Scotsman*. Professor Cossar Ewart regards these sheep as belonging to a hybrid race, which has arisen from the mating of ancestors belonging to the wild urial and mouflon types of sheep, the former of which is still found from Eastern Persia to Tibet, while the latter appears to be confined at the present day to Western Asia, Corsica, Sardinia, and Sicily. Dr. Ritchie does not comment upon their origin in the contribution he makes to the *Scottish Naturalist*, but states two facts—first, that four-horned sheep belong to an exceedingly old type, for their remains have been recovered from deposits of the Bronze Age; and, secondly, that the type has been a stable and predominant one, for nowadays it is to be found scattered over most parts of the world, and recent experiments in crossing show that the progeny of a four-horned ram is almost certain, in one generation or another, to exhibit this parental peculiarity.

**United Kingdom Wheat Imports.**

The question of foodstuffs is of imperative importance to the people of the United Kingdom at the present juncture. In 1913 the imports of wheat in the grain amounted to 55,141,000cwts. from foreign countries and 50,737,000cwts. from British possessions, while the corresponding figures for wheat and flour, taken together in equivalent of grain, were 65,500,000cwts. from foreign countries and 57,014,000cwts. from British possessions.

**Imports and Exports of Fruits, Plants, Etc.**

During the month of August, 1914, 1,470bush. of fresh fruits, 11,054bush. of bananas, 14,600 bags of potatoes, 916 bags of onions, 121pkgs. vegetables, and 238pkgs. plants, trees, and bulbs were examined and admitted at A<sup>3</sup> laide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910. Fifty-two packages of bananas (over-ripe) and 1pkg. of plants (no phylloxera declaration) were destroyed. Under the Federal Commerce Act, 1,146 cases of fresh fruits, 861pkgs. dried fruit, and 139pkgs. preserved fruit were exported to oversea markets during the same period. These were distributed as follows:—For New Zealand, 703 cases lemons, 351 cases oranges, 810pkgs. of dried fruit, and 25pkgs. preserved fruit; for London, 92 cases oranges and 1pkg. dried fruit; for India, 114pkgs. preserved fruit; for Canada, 50pkgs. dried fruit. Under the Federal Quarantine Act 656pkgs. of plants, bulbs, seeds, nuts, &c., were examined and admitted from oversea markets.

## INQUIRY DEPARTMENT.

---

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture, Adelaide.*"

### STOCK INQUIRIES.

Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.

"A. E. M.," Leighton, has a mare which he bought in Adelaide, and which subsequently suffered from itchy legs. He asks for treatment.

Reply—Probably change of climate has something to do with the itching, which causes the mare to bite her legs and cause sores. It would be a good plan to prepare her with bran mash for two days and then give her a 6-dram aloes purge. When the effects have worn off a daily dose of a tablespoonful of sulphur will do her good. Probably it would be better to keep water away from her legs, and use one part benzine to five parts olive oil instead, as no doubt there are also skin parasites affecting the legs.

"A. B. O.," has mare, 8 years, which was born with bandy front leg and pigeon-toed; now has enlarged fetlock and is very lame. He asks could anything be done to enable her to be kept for breeding?

Reply—Such a mare is eating food that would keep a working animal, and the most profitable course would be to destroy her.

"J. R. J." asks treatment for light buggy mare which is in good condition but will eat fresh manure.

Reply—This habit indicates indigestion, and once formed is difficult to break. Muzzle her when in the yard; give a tablespoonful of charcoal in the morning's feed and a cupful of limewater in the evening, daily. A good dose of physic—a 5-dram aloes ball—to clear her out would help.

"F. W. J. C.," Waikerie, has cow which has been ill for nine months. She calved in July, 1913, and fed on spear grass and piemelon; in September last she got lucerne. Three weeks afterwards went off her feed and one day ate a very rotten pumpkin. Gradually became stiff over loins, was con-

tinually lying down and shifting her legs; milk fell off, skin became shiny, and dung black, soft, and scanty. She would stand for hours with head down, her eyes being glaring and glassy, and there was constant running at nose and heaving at flanks. Temperature was variable. When down she placed head on hind legs and was constantly grinding her teeth and yawning; when standing her back was hunched. For two months she could hardly walk, and subsequently all hair on tail came off, teeth became loose, and feet were extremely sore; she had a cough, and now hoofs are coming off. She was treated, but has not recovered.

Reply—This is a splendid example of the information required to enable a diagnosis to be arrived at. The cow suffers from one form of dry bible, namely, scurvy, and it is doubtful whether she will repay her owner's attention. However, for treatment let her have two or three lemons daily, or a teacup of limejuice, and once a week a pint of yeast; if this is not available a packet of dry yeast or 2lbs. of currants. Further information as to her progress will be received with interest.

"J. C. S." asks treatment for mare, 5 years, which is in good condition and has fine coat, but eats bark off rails, &c.

Reply—A sign of indigestion. It would be well to give her bran mash only for two days and then give her a 6-dram physic ball (obtainable from the chemist). When this has ceased to purge her, in about 24 hours, it would be well to give her a tablespoonful of charcoal once a day mixed in her feed, also a teacup of limewater in her feed each evening.

"A. K. W.," Tintinara, asks advice concerning horse which went lame. Examination showed a hole at right side of frog on off fore leg, from which matter exuded.

Reply—Trodden on stump. Make sure nothing is in hole; soak well in hot water with an ounce of bluestone to gallon, then put on tar and tow; cut corner off bag, put foot in and tie round fetlock with tape or strip of bag, not cord, which would stop circulation; repeat daily as often as necessary.

"F. B." asks advice concerning horses which, when put into paddock of green feed, became stiff, but got better in few days. When turned into fresh paddock, however, trouble reappeared, and one mare died.

Reply—Probably contagious pneumonia; 20 drops of tr. nux vomica twice daily on tongue would help.

"T. S.," Forster, asks if there is anything which will prevent horses' hair turning white through scalds.

Reply—There is nothing that will prevent the hair from becoming white, but it may be colored with strong solution of permanganate of potash (Condy's crystals).

"J. R. M.," Yarcowie, seeks treatment for filly, three years, which has gone off feed, is scoured very badly, and weak.

Reply—The symptoms seem to point to a bad infestation of worms. Treatment—Half-pint of castor oil, feed pollard, stop molasses; twice daily on the tongue a tablespoonful of syrup of phosphate of iron. The chance of recovery is not favorable.

“A. J. M.,” Yeelanna, has a stallion which is not a hearty eater. He asks advice concerning ration during season.

Reply—It is difficult to quote a diet for any animal without seeing him, as size, age, constitution, and other factors have to be considered; but the following is theoretically what he wants:—Chaff, 20lbs.; hay, 10lbs.; oats, 6lbs.; peas, 3lbs.; divided into four feeds daily, the hay being given at night. Lucerne may be substituted for it when available, and wheat or barley may take the place of some of the oats, while on Saturday and Sunday bran may be given instead of peas. If thought desirable any of the proprietary condiments may be given, their chief use is to flavor the food, or a tablespoon of the following mixture may be given twice a day:—Salt, one part; pepper, one part; aniseseed or foenugreek, one part; linseed meal, three parts. Drugs supposed to have an aphrodisiac effect on an animal are to be avoided—they defeat their own end.

“B. B.” had mare which became suddenly ill; symptoms pointed to stoppage water, with severe pain. He administered nitre and then chlorodyne, which relieved a little. Subsequently he covered animal with dung, which caused her to sweat and she recovered. He asks—Was trouble caused by a chill?

Reply—Yes; a chill after hard work was probably the cause. The remedies, nitre and chlorodyne, were correct. A good rubbing would have been easier than burying her in dung, but it was right to get her warm.

“R. W. C.” has horse which has lost hair off mane and back through disease which is very irritating. He has boiled tobacco, added sulphur, and bathed with mixture; dosed with Epsom salts, and put horse on green feed. He asks if treatment is correct.

Reply—It is mange, and your treatment is all right, but this form is very hard to cure. If you do not succeed, bring him out in the sun and lather the parts well with soft soap and hot water, leave it on to dry; a few hours after wash off with water and soda, then dress with benzine one part and any cheap oil five parts. Do this once a day for three days, then once a week for three weeks.

“A. McD.,” Stirling East, asks cause of bare patches on pig's neck and thigh, with apparently great itching, and whether disease is infectious?

Reply—Probably ringworm, in which case it is infectious but not dangerous. Wash the places well with soap and put on sulphur ointment after. Give a dessertspoon of sulphur in food once a day for a week.

"P.," Cressy, asks reason for horses continually lying down, sitting up, and then rolling.

Reply—Bowel indigestion and sand. Treat for the latter and then give 10 drops tr. nux vomica in feed or on tongue twice a day for a fortnight.

"H. C.," Mount Compass, has mare, 5 years, which is in good condition but has dry cough, especially after exertion.

Reply—Probably due to cutting the last four molar teeth. Stockholm tar on the bit is a very good remedy for cough generally. If the cough does not pass off try a little embrocation rubbed into the throat.

"R. J. S.," Harrogate, asks treatment for pony which is continually scouring, whether on dry or green feed.

Reply—Probably there is no satisfactory cure for an aged pony; there is probably some chronic irritation of the bowels. Ten drops tr. arsenicum morning and evening in the feed for a month might effect an improvement, but it is doubtful.

"P. N. P.," Wirrega, asks treatment (not drenching) for horses suffering from sand.

Reply—Sand powders often consist of equal parts sulphur, cream of tartar, and powdered nux vomica; the dose is a dessertspoonful once a day for a week or so. The powder will be more effective if an equal part of grated areca nut is added.

"R. T. H." asks cause of death of horse which was ill for 10 days. The animal would just shift about and nibble at green feed, would not touch dry feed, and gradually pined away, standing till it died; it seemed to lose power of hindquarters, and was hollow in flanks. It was drenched.

Reply—The symptoms are those of a bad attack of bloodworms combined with inflammation of the lungs, which possibly was not altogether unconnected with the drench, some having gone the wrong way.

"J. H. B.," Appila-Yarrowie, asks advice concerning mare, five years old, which for last six months has had increasing growth on third eyelid.

Reply—This is a form of cancer, started in the first place by the irritation of flies, the treatment is to have it cut out and the place cauterised; it is a case for a qualified veterinary surgeon to take in hand. In the mean time blow a little dry boracic acid into the eyelid once or twice a week.

"J. B. T.," Sutherlands, has a mare, five years, which when at work breathes very heavily. There is no discharge from nose or eyes, but he has been told it may be a case of hidden strangles. He asks if this is possible, and for treatment.

Reply—Possibly hidden or bastard strangles, as suggested, which does not always produce a discharge from the nose and eyes, but more probably result of congestion of the lungs. Spell the mare for a time, and give 10 drops of tincture arsenicum twice a day in the feed for a week or 10 days.

Of course, there are probably worms and bots present, but they as a rule do not affect the breathing.

"E. S.," Steelton, has mare which, after being put on stubble feed with native clover, suffered from intermittent attacks of colic, not very painful; in the intervals she was lively. She was at first treated with oz. soda in each feed, and then dosed with aloes in linseed oil.

Reply—The change of feed is the cause of the trouble, and the symptoms point to impaction of the colon, probably from previous feed, possibly from worms also. The treatment has been all right so far, but she would probably benefit by having 10 drops of tincture nux vomica twice daily for a week or so, put in feed or on tongue.

### HORTICULTURE.

"L. Z." asks—(1) The time to irrigate apricot, peach, and orange trees; (2) the best means to protect the bark of young orange trees from heat; (3) how to prune orange trees; and (4) how to irrigate an orchard.

The Horticultural Instructor (Mr. Geo. Quinn) replies:—(1) In respect to the two former kinds it is safe during ordinary seasons to apply water to them at any time excepting when in bloom or after the fruit starts to soften in ripening. Of course one must consider the condition of the soil in respect to moisture and drainage. In an ordinary winter the soil usually holds enough moisture to keep the roots fresh and plump, but during seasons such as the present this is not the case, and the soil needs moistening by irrigation, even in what should be midwinter. I advise you to give the sub-soil a good soaking now (before they bloom) under these circumstances. If the season continues dry give them another after the fruits reach the size of large grape berries, and in the absence of rain another watering when the fruits are about three-parts full-grown. Should the autumn continue dry it will be necessary to give them a watering to fill up the buds for next season's fruit; but this should be given soon after the fruit is gathered so as to allow the buds to mature gradually. The orange trees, if of mature size, need watering about every five or six weeks during the summer months unless heavy rains fall. Particular attention must be given to see these trees do not stand in dry soil while the crop is coming to maturity, say from April to July. In ordinary seasons the rainfall will often prove sufficient for this purpose, but this has not been the case during the past couple of years. Do not water these trees when in full bloom, but rather just before they burst into blossom—if the soil demands moisture. The great secret of keeping the orange in good condition is not to let the soil about the roots get dry and not to allow it to become stagnant with too much wetness, particularly in the cold months of the year. Do not, however, wait until the trees wilt, but test the soil itself for moisture over the area wherein you know the roots are searching for plant food materials, and regulate the applications of irri-

gation water accordingly. (2) If the bark on the stems of young orange trees have suffered from exposure to heat the best remedy is found in covering them with straw tied not tightly around the stems. Strips of bagging wound loosely around from the ground line upwards will also afford good shelter. Lime-washing may, with advantage, be applied to the stems and limbs of older trees, the foliage of which is too scanty to afford them the necessary shade. (3) The pruning of the orange consists largely of shaping the tree from the branches it sends out. Personally, I prefer to merely thin out densely crowded twigs to admit light and air and keep down pests; but care must be exercised not to throw the trees sufficiently open to permit sun-scalding of the bark of the limbs. Crossing limbs must be suppressed early, and the general balance of the tree regulated from time to time. As the outer limbs reach the ground they should be cut back either to where a bud or shoot is found on the upper surface of the bent limb, thus giving the growth an upward tendency. This is sometimes begun after the first few fruits have been borne. As the trees reach a mature size keep all the water shoots arising from the stem or limbs cut out so that the internal supporting framework of the tree is free from such growth, and when viewed from beneath is clearly outlined like the ribs and handle of an expanded umbrella. (4) There are several methods of applying water to the land occupied by trees. Which of these to adopt depends largely on the volume of water and the nature of the soil—

- (1) Ring System.—This consists of making a ring or saucer around each tree, say, outside the spread of the foliage, and filling it with water once or more at each irrigation.
- (2) Basin or Check System.—This consists of making groups of trees into plots surrounded by low banks, beginning at the upper side of the block. After one basin has been filled and soaked the water is drawn off into a lower one, and so on. This necessitates flooding the surface of the soil very much, and is not recommended.
- (3) Furrow System.—This method consists of making furrows between the trees and passing the water slowly down them, allowing it to soak away in sufficient quantities. For young trees a furrow made each side of the rows of trees, say a couple of feet out from the trees, will be sufficient; but as the tree extends in root area the whole of the land it occupies must be supplied by increasing the number of furrows to about three between each two rows, as well as "fish boning" across the spaces between the trees in the rows. These furrows should be deep, so that the water is put down to the roots. A day or two after the watering, when the wetted soil loses its stickiness, it should be thoroughly stirred up right to the bottom of the furrows, and the whole surface levelled down into a loose, deep, finely pulverised mulch.

“ J. P.” asks the best way to obtain Northern Spy apple stocks.

Mr. Quinn states—“ The usual method of obtaining blight-proof apple stocks consists of grafting a piece of root of a blight-proof sort, such as Northern Spy, on to a shoot of the same kind, and when it grows to bud or graft on to it, say about 6in. above ground, the kind of apple desired. The procedure is as follows :—Take pieces of about as thick as a penhandle, and 4in. to 6in. long, from any apple tree grafted on a blight-proof stock—the Northern Spy for preference—and graft on to them by the whip or tongue joint pieces of the last season’s top growth of a Northern Spy apple, using these scions about 6in. or 8in. long. The joint is tied with candle cotton raffia, or any kind of soft binding which will rot in the soil. Set the grafted plants in soil of a free, sweet, sandy nature, at such a depth that only one or two buds on the top of the scion are above ground. Keep the bed cool and moist as the summer comes on, and when the shoot which arises from the scion is as thick as a lead pencil it may be budded to the kind required. The roots and scions are grafted, say, in June, July, or August, according to the earliness or lateness of the locality ; planted out at once, and the budding of many may be done in the following February. If these buds unite the tops of the stock above them will not be cut off until early in the following spring, say August. Cuttings of apple trees do not root freely, but if your cuttings which formed lumps of callus on their bases had been lifted and the callus been slightly scraped here and there, and the cuttings planted again immediately, roots would most likely have emerged from the scratched spots.”

#### SUMMER CROP FOR KAROONDA DISTRICT.

“ C. E. B.,” Karoonda, seeks information as to best crop to sow in his district for early summer feed for horses. He asks—“ Would Japanese millet be suitable ? ”

The Director of Agriculture (Professor Perkins) replies :—“ I am afraid that you will find that your district is too short of summer rains to be suitable for Japanese millet, and in my opinion the only summer crop that can be safely recommended is ordinary sorghum, preferably the Early Amber Cane variety ; but even this crop is not likely to succeed unless some summer thunderstorms come opportunely. If possible, sowing should be deferred until the first heavy rain, because it is not wise to leave the seed lying in the land for any length of time. Moreover, if a crust forms over the seed it is apt to interfere with the regular germination of the crop. I suggest, therefore, that seeding take place some time in September, preferably immediately after rain. The crop, however, might be sown in October if conditions appear favorable in that month. Sow the seed at the rate of

5lbs. or 6lbs. to the acre, mixing it thoroughly with about  $\frac{1}{2}$  cwt. of well-ground bonedust, and passing the seed and manure through the manure tubes. The rows should be sufficiently far apart to permit of summer cultivation. Say in a 7in. drill, block three of the openings so as to leave the rows 28in. apart. One should be careful not to drill the seed in too deeply. The sorghum will thrive best on light land, but will give the best results if the ground has been dressed to a certain extent with good farmyard manure. Avoid feeding off the crop before the heads begin to form, since in its immature stage it is apt to become poisonous to live stock."

---

## FOOD SUPPLY OF UNITED KINGDOM.

---

### WHERE PROVISIONS ARE OBTAINED.

---

Dealing with the provisioning of the United Kingdom, *The Times* in a leading article contained in a special food supplement published on June 8th, states, *inter alia*—

"The story of the provisioning of these crowded islands of ours is one of the marvels of the world. The great fleets of merchant vessels that bring the provisions to our ports, the warehouses and markets in which they are stored and sold, the varied processes by which they are prepared and preserved for our use—each and all of the separate departments of our commerce in perishable goods are buzzing hives of human industry and rich in human interest. To every member of the community, together with the ever-changing conditions of the international trade in food and the economic laws by which it is governed, they are matters of supreme importance.

"The first and most obvious of these laws and conditions to which this country is subject is dependent on the density of its population and the comparative smallness of the amount of food which its inhabitants produce for their own consumption. Because of these two factors the foreign produce which we import is by far the largest item in our national food bill. We import our food from practically every country on the face of the globe, to the value of 275 millions sterling per annum, rather less than a third of which is credited to British overseas possessions. The largest individual

contribution to this amount, £35,000,000 worth of food, comes from Argentina. Of other countries outside Europe the United States comes next with about two millions less, followed by India with 25 millions, Canada with 20, Australia with 14, and New Zealand with 10 millions; and so on through a long list of 80 or 90 separate countries, down to Afghanistan's modest contribution of £636 worth of dried raisins. In these bills (the figures given are those for 1912) the largest amounts that we paid to the respective countries were for meat from Argentina, wheat and tea from India, wheat from Canada, wheat and meat from Australia, mutton from New Zealand, and wheat and bacon from the United States. There is still one figure to be added which surpasses all the rest in interest, not on account of its magnitude, but for precisely the opposite reason, and because of the tendency which it indicates. Eight years ago our imports of chilled and frozen meats from the United States were valued at over £5,000,000. In 1912 they had sunk to £15,000. This is by far the most striking change that is at present taking place in the food trade conditions of the world. It means that the once great export meat trade of the United States is now practically non-existent, and that unless the Americans take steps to increase their home production of this staple article of food they will not only cease to export, but will become to an increasing extent rival buyers in the markets of the world with ourselves and other nations. We are also threatened with the same menace in the egg trade by the United States and Germany, both of which, instead of being able to supply their own demand for eggs, are now buying from Denmark and Russia and other countries from whom we have hitherto derived supplies.

"In Europe there are three countries—Denmark, the Netherlands, and Germany—each of which exports to us food to the value of 10 millions sterling or more. Of these the Danish and Dutch totals of 21 and 14 millions are the most remarkable. It is indeed almost incredible that Denmark, one of the smallest countries of the world, should be able to supply us with food (chiefly butter and eggs) worth more than the quarter of the value of our food imports from all the British possessions abroad, even though some allowances must be made for the fact that Denmark draws from Russia part of the supplies which she afterwards exports to this country. Nearer home the case of Ireland is even more striking. Not many people realise that (even under the despised Union) she is Great Britain's largest provisioner, with a total of £30,000,000 worth of food per annum. In 1912 she supplied the sister island with two million pounds' worth more meat than Argentina, with more butter than any country but Denmark, more eggs than any but Russia, and four times as much poultry as her nearest competitor in the trade.

"The general reflection inevitably suggested by a consideration of the above facts is the alarming extent of our dependence on foreign imports. Year by year it increases. With the exception of sugar, which for various

reasons remains at the same figure of £25,000,000, the respective values of our principal imported foods from all countries, reckoned in millions of pounds sterling, have during the last 20 years risen as follows :—Wheat from 25 to 45, butter from 13 to 25, bacon from eight to 20, beef from four to 20, mutton from five to 10, fruit from five to 11, and eggs from four to nine millions. That is undoubtedly a disquieting state of affairs. In reality not much comfort is to be gleaned from the apparently hopeful examples of Ireland, Denmark, and Holland. If the British Isles produced as much food in proportion to their size as the last of these countries, they would have more than enough for their wants. They could even become food exporters instead of buying from abroad. There seems, however, to be little chance of this ideal being realised. At present we produce less than one-fifth of the wheat which we consume, and the opinions of experts do not encourage the idea that wheat-growing on a more extensive scale can be made a paying proposition. The tendency, in fact, is all the other way. The acreage of arable land in this country grows less every year, as does also (in the first two cases largely by reason of the diminution of arable land) the number of cattle and sheep and pigs. It is only in the production of butter, milk, eggs, poultry, and vegetables that we can hope to make the home supply match our needs. That is an undertaking well within our powers."

Baling Straw, Roseworthy.

## ADVANCE OF AGRICULTURE.

---

### WINNING NEW LANDS.

---

[Address by Mr. A. D. HALL, M.A., F.R.S., President Agricultural Section, British Association for the Advancement of Science.]

Probably the most interesting, so far as the farmer is concerned, of the addresses delivered in connection with the Adelaide session of the British Association for the Advancement of Science was that given by the President of the Agricultural Section (Mr. A. D. Hall, M.A., F.R.S.). Mr. Hall, who is now a Commissioner under the English Development Act, and who was formerly Director of the Rothamsted Experimental Station, dealt mainly with the winning of new land for agriculture. He said :—

The president of a section of the British Association has two very distinct precedents before him for his address ; he can either set about a general review of the whole subject to which his section is devoted or he can give an account of one of his own investigations which he judges to be of wider interest and application than usual. The special circumstances of this meeting in Australia have suggested to me another course. I have tried to find a topic which under one or other of its aspects may be equally interesting both to my colleagues from England and to my audience who are farming here in this great Continent. My subject will be the winning of new land for agriculture, the bringing into cultivation of land that has hitherto been left to run to waste because it was regarded as unprofitable to farm. To some extent, of course, this may be regarded as the normal process by which new countries are settled ; the bush is cleared and the plough follows, or under other conditions the rough native herbage gives way to pasture under the organised grazing of sheep or cattle. I wish, however, to deal exclusively with what are commonly termed the bad lands, inasmuch as in many parts of the world, though recently settled, agriculture is being forced to attack these bad lands because the supply of natural farming land is running short. In a new country farming begins on the naturally fertile soils that only require a minimum of cultivation to yield profitable crops, and the new-comers wander further afield in order to find land which will in the light of their former experience be good. Before long the supply is exhausted, the second-class land is then taken up until the stage is reached of experimentation upon soils that require some special treatment or novel form of agriculture before they can be utilised at all. Perhaps North America affords the clearest illustration : its

great agricultural development came with the opening up of the prairies of the Middle West, where the soil rich in the accumulated fertility of past cycles of vegetation was both easy to work and grateful for exploitation. But with the growth of population and the continued demand for land no soils of that class have been available for the last generation or so, and latterly we find the problem has been how to make use of the arid lands, either by irrigation or by dry-farming where the rainfall can still be made adequate for partial cropping, or, further, how to convert the soils that are absolutely poisoned by alkali salts into something capable of growing a crop. You yourselves will supply better than I can the Australian parallels, at any rate we in England read that the wheat-belt is now being extended into districts where the low rainfall had hitherto been thought to preclude any systematic cropping.

Now, the fact that the supply of naturally fertile land is not unlimited reacts in its turn upon the old countries. During the 'eighties and 'nineties of the last century the opening up of such vast wheat areas in America, Argentina, Australia, and the development of the overseas trade reduced prices in Europe to such an extent that in Great Britain, where the full extent of the competition was experienced, the extension of agriculture came to an end despite the continued increase of population. The area of land under cultivation has declined but little despite the growth of the towns, but the process of taking in the waste lands stopped and much of the land already farmed fell back from arable to cheaper pasture. But as soon as production in the newer countries failed to keep pace with the growth of population prices began to rise again, and we are now in the old world endeavoring to make productive the land that has hitherto been of little service except for sport and the roughest of grazing. Even the most densely populated European countries contain great areas of uncultivated land; within 50 miles of London blocks of a thousand acres of waste may be found, and Holland and Belgium, perhaps the most intensively cultivated of all Western countries, possess immense districts that are little more than desert. Of the European countries, Germany has taken the lead in endeavoring to bring into use this undeveloped capital; her population is rising rapidly and her fiscal policy has caused her to feel severely the recent increase in the prices of foodstuffs, which she has determined to relieve, as far as possible, by extending the productivity of her own land. It has been estimated that Germany possesses something approaching to 10,000,000 acres of uncultivated land, and a Government department has been created to reclaim and colonise this area.

#### AN IMPORTANT QUESTION.

Before dealing with the processes by which the rough places of the earth are to be made straight there is one general question that deserves consideration—Is it more feasible to increase the production of a given country by enlarging the area under cultivation or by improving the methods of the

existing cultivators ? There is without doubt plenty of room for the latter process even in the most highly farmed countries : in England the average yield of wheat is about 32bush. per acre—a good farmer expects 40 ; the average yield of mangolds, a crop more dependent upon cultivation, is as low as 20 tons per acre when twice as much will not be out of the way with good farming. A large proportion of the moderate land in England is kept in the state of poor grass—even as grass its production might be doubled by suitable manuring and careful management, while under the plough its production of cattle-food might easily be trebled or quadrupled. Why, then, trouble about adding to the area of indifferent land when so much of what has already been reclaimed, upon which the first capital outlay of clearing, fencing, road-making, etc., has been accomplished, is not doing its duty ? We are at once confronted by the human factor in the problem. The existing educational agencies which will have to bring about better farming will only slowly become effective, and however imperfect they still may be in England, they are mainly so because of the lack of response upon the part of the farmers. The present occupiers of the land do obtain in many cases a very inadequate return from it, but they make some sort of a living and they hold it up against others who, though they want land, cannot be guaranteed to use it any better. Improved farming means more enterprise, more knowledge, often more capital, and the man who can bring these to the business is far rarer than the man who, given a piece of land even of the poorest quality, will knock a living out of it by sheer hard work and doggedness. While, then, there should be no slackening in our efforts to improve the quality of the management of existing land, there is a case for also using every effort to increase the cultivable area ; indeed, it is probable that for some time to come the second process will add most to both the agricultural production and the agricultural population.

#### FACTORS FOR FERTILITY.

Let us now consider what are the factors which determine the fertility of the land that is first brought into cultivation and remains the backbone of farming in the old settled countries. Foremost comes rainfall, and the distribution is almost as important as the amount. Winter rain is more valuable than summer, and though cereal-growing is none the worse and may even obtain better results with a rainless summer, stock-raising and the production of fodder crops are the better for a rainfall that is distributed fairly evenly throughout the year. Rainfall, again, must bear some relation to temperature ; some of the best farming in the eastern counties of England is done on an average rainfall of 20in. ; there are great areas in South Africa with the same average rainfall that are little better than desert. In temperate regions we may say that the naturally fertile land requires a rainfall of from 20in. to 50in. per annum, not too much segregated into seasons and some at least falling in the winter.

If the rainfall is excessive or the drainage inadequate to carry it off, the formation of peat is induced, resulting in such uncultivated areas as the bogs of Ireland and the moors of Eastern England, Holland, and Germany.

Given suitable rainfall and temperature the texture of the soil becomes a factor of importance ; if too coarse and sandy, so little of the rainfall is retained that we get all the effects of drought secondarily produced. In itself the open texture of a coarse sandy soil is favorable to plant development ; under irrigation, or where the situation is such as to result in permanent water a short distance below the surface, fine crops will be produced on sandy soils that would remain almost barren if they only depended upon the rainfall for their water. In Western Europe large areas of heaths and waste land owe their character to the coarse and open texture of the soil. At the opposite extreme we find clays so heavy that their cultivation is unprofitable ; such soils, however, will carry grass and are rarely left unoccupied. For example, in the south-east of England there are a few commons, *i.e.*, land which has never been regarded as worth enclosing and bringing into particular ownership, situated on heavy clay land ; most of such land is pasture, often of the poorest, or, if at any elevation, has been covered with forest from time immemorial.

One last factor in the soil is of the utmost importance to fertility and that is the presence of lime—of calcium carbonate, to be more accurate—in quantities sufficient to maintain the soil in a neutral condition. Old as is the knowledge that lime is of value to the soil, we are only now beginning to realise, as investigation into the minute organisms of the soil proceeds, how fundamental is the presence of lime to fertility. A survey of the farming of England or Western Europe will show that all the naturally rich soils are either definitely calcareous or contain sufficient calcium carbonate to maintain them in a neutral condition even after many centuries of cultivation. Examples are not lacking where the supply of calcium carbonate by human agency has been the factor in bringing and keeping land in cultivation. I have discussed one such case on the Rothamsted Estate, and several others have come under my notice. The amelioration of non-calcareous soils by treatment with chalk or marl from some adjacent source has been a traditional usage in England and the North of France : Pliny reports it as prevailing in Gaul and Britain in his day, and the farmer of to-day often owes the value of his land to his unknown predecessors who continuously chalked or marled the land. Upon the presence of carbonate of lime depends the type of biological reaction that will go on in the soil, the beneficial bacterial processes that prepare the food for plants only take place in a medium with a neutral reaction. The Rothamsted soils have provided two leading cases. I have shown that the accumulation of fertility in grass-land left to itself and neither grazed nor mown, so that virgin conditions were being re-established, was due to the action of the organism called *Azotobacter*, which fixes free nitrogen from the atmosphere, and was indirectly determined by the presence of calcium carbonate in the

soil, without which the *Azotobacter* cannot function. Examination of typical examples of black soils from all parts of the world, the prairies of North America, the steppes of Russia, and the Argentine, New Zealand and Indian soils, showed in all of them the *Azotobacter* organism and a working proportion of carbonate of lime. Now, as we know, all virgin soils are not rich, and only in a few parts of the world are to be found those wonderful black soils that are often several feet in depth and contain 10 to 20 per cent. of organic matter and three to five parts per 1,000 of nitrogen. These soils are all calcareous, they occur in regions of a moderate rainfall inducing grass-steppe or bush conditions, and the annual fall of vegetation provides the organic matter which the *Azotobacter* requires as a source of energy in order to fix nitrogen. Non-calcareous soils under similar climatic conditions do not accumulate nitrogen and become rich; in the absence of carbonate of lime the nitrogen-fixing organisms are not active, and the soil only receives from the annual fall of vegetation the nitrogen that was originally taken from it. There is but a cyclic movement of nitrogen from the soil to the plant and back again, whereas in the calcareous soils there is also continuous addition of fresh nitrogen derived from the atmosphere, in which process the carbonaceous part of the annual crop supplies the motive power.

The other leading case to be found at Rothamsted is that of certain grass-plots which have artificially been brought into an acid condition by the continued application of sulphate of ammonia. In these soils nitrification is suspended, the nitrification organisms have even disappeared, though the herbage still obtains nitrogen because most plants are able to utilise ammoniacal nitrogen as well as nitrates. The interesting feature, however, is that the decaying grass on these acid soils passes into the form of peat, a layer of which is forming upon the surface of the soil, though nothing of the kind is found on adjacent plots where the use of lime or of alkaline manures has prevented the development of acidity. From this we may learn that the development of a surface layer of peat, independent of waterlogging (when another kind of peat forms even under alkaline conditions), is determined by the acidity of the soil, when certain of the bacterial processes of decay are replaced by changes due by micro-fungi which do not carry the breaking-down of organic matter to the destructive stage. This affords us a clue to the origin of many areas of upland peat in the British Isles, where the remains of ancient forest roots and stumps of trees are found on the true soil surface below the layer of peat, but where there is no water-logging to bring about the death of the trees and the formation of peat. We may suppose that when the land-surface became fit for vegetation at the close of the glacial epoch it covered itself with a normal vegetation, chiefly dwarf forest, because of the rainfall and temperature. The soil, however, being without carbonate of lime, would in time become acid with the products of decay of the vegetable matter falling to the ground, and as soon as this acid condition was set up

peat would begin to form from the grassy surface vegetation. The process would continue until the acid conditions and the depth of the accumulating layer of peat would kill the trees, the stumps of which would remain sealed up below the peat. I am far from thinking that this explanation is complete, but at least we have facts in sight which could lead one to suppose that a non-calcareous soil originally neutral and carrying a normal vegetation can naturally become acid, alter the character of its vegetation and clothe itself with a layer of peat. The point of economic importance is that these peaty acid soils are of very little value as long as they are acid, though they take on a quite different aspect if they are limed and made neutral.

Of all the soil factors making for fertility I should put lime the first ; upon its presence depend both the processes which produce available plant food in quantities adequate for crop-production at a high level and those which naturally regenerate and maintain the resources of the soil ; it is, moreover, the factor which is most easily under the control of the agriculturist.

I need say little about those cases in which infertility is due to the presence in the soil of some substance which is actually injurious to plant-growth, because such substances are nearly always due to the physical environment of the soil, to too much or too little water. In waterlogged situations we may find in the soil peaty acids, iron salts, sulphides, &c., inhibiting the growth of plants ; in arid regions the soil may still be charged with an excess of soluble compounds of the alkalis and alkaline earths, resulting from the decomposition of the rocks that have been broken down to form the soil, but which through the inadequate rainfall have never been washed out. The establishment of normal conditions of growth, irrigation in the one case, drainage in the other, will speedily result in the removal of the deleterious substances. Practically, only bodies that are soluble can get into a plant to injure it, hence such bodies can be removed from the soil by water, provided that the water can find its way through the soil and escape.

#### DRY-FARMING.

Let us now consider the various methods by which land suffering from one or other of the disabilities we have just discussed is nowadays being brought into cultivation. The most important, if we consider the area affected, is the extension of cropping into regions of deficient rainfall by means of what has been termed dry-farming. As far as its immediate methods go, dry-farming consists in nothing more than the application of the principles of husbandry worked out by English farmers in the east and south-east of England, principles first expounded by Jethro Tull, though a complete explanation was not then possible, even if it is now. In the first place, the tilth must be made both deep and fine, thus whatever rain falls will be absorbed and the conditions favoring a deep and full root range will have been established. Next, the soil below the surface, though finely worked, must be compact, because only

thus can the water present travel to the roots of the plant. Lastly, a loose layer must be maintained on the surface, which, though dry itself, acts as a screen and a barrier to prevent loss of water from the effective soil below by any other channel than that of the plant. Granted these methods of cultivation, the new feature about "dry-farming," which has been introduced by settlers in the arid districts of Australia and North America, is the use of a year of bare fallow in which to accumulate a supply of water for the next year's or two years' crop. This raises the fundamental question of how much water is necessary for the growth of an ordinary crop. The first investigation that Lawes and Gilbert carried out at Rothamsted dealt with this very point; they grew the usual field crop in pots, protected the surface of the soil from evaporation so that all the loss of water proceeded through the plant, weighed the water that was applied from time to time, and finally weighed the produce, expressing their results as a ratio between the dry matter produced and the water transpired by the plant. These experiments have been repeated under different climatic conditions by Hellriegel in Heidelberg, by Wollny in Vienna, by King and others in America. Now the two processes in the plant, carbon assimilation and transpiration, are not casually connected, though as both are carried out in the leaf and have some factors in common they are found to show some constancy in their relative magnitudes. Lawes and Gilbert obtained a ratio of about 300lbs. of water transpired for each pound of dry matter harvested, but the other investigators under more arid conditions found much higher figures, up to 500 and even 700 to one. Now, a crop yielding 20bush. of wheat per acre will contain about a ton of dry matter per acre, so that, taking the high ratio of 500 to one, no more than 500 tons of water per acre or 5in. of rain will have been consumed in the production of this crop. It is, of course, impossible to ensure that all the rain falling within a year shall be saved for the crop; much must evaporate before it reaches the subsoil where it can be stored, and only when the crop is in full possession of the land can we expect that all the water leaving the soil shall go through the crop. What proportion the waste bears to that which is utilised will depend not only on the degree of cultivation but upon the season at which the fall occurs; summer showers, for example, that do not penetrate more than a few inches below the surface will be dissipated without any useful effect. When the climatic conditions result in precipitation during the winter, the water will be in the main available for crop-production; and it has been found by experience that cereals can be profitably grown with as small a rainfall as 12in. The necessary cultural operations consist in producing such a rough surface as will ensure the water getting into the subsoil, hence autumn ploughing is desirable. Where the precipitation is largely in the form of snow, a broken surface also helps both to absorb the thawing snow and to prevent it being swept into the gullies and hollow places by the wind. On some of the Russian steppes it has become customary to leave a long stubble in order to entangle as much snow as possible, but probably a rough ploughing before the

snowfall would be even more effective. When the rainfall drops to the region of 12in. to 16in. and occurs during the summer months, then dry-farming methods and the summer fallow become of the first importance. The deep cultivation ensures that the water gets quickly down to the subsoil away from danger of evaporation, and the immediate renewal of a loose surface tilth is essential in order to conserve what has thus been gained.

In connection with this dry-farming there are several matters that still require investigation before we can decide what is the minimum rainfall on which cultivation can be profitable. In the first place, we are only imperfectly informed as to the relation between rainfall and evaporation. At Rothamsted there are three drain-gauges side by side, the soil layers being 20in., 40in., and 60in. deep respectively. The surface is kept rough and free from growth, though hardly in the condition of looseness that could be described as a soil mulch. Yet the evaporation, even under a moist English atmosphere, amounts to one-half of the annual rainfall, and the significant thing is that the evaporation is approximately the same from all of the gauges and is independent of the depth of subsoil within which water is stored. Evaporation then would seem to be determined by surface alone, but we are without systematic experiments to show how variations in the surface induced by cultivation will alter the rate of evaporation. A knowledge of the evaporation factor would then inform us of what proportion of the rainfall reaches the subsoil; we then want to know to what extent it can be recovered and how far it may sink beyond the reach of the crop. It is commonly supposed that the subsoil below the actual range of the roots of the crop may still return water by capillarity to the higher levels that are being depleted, the deeper subsoil thus acting as a kind of regulating reservoir absorbing rain in times of excess and returning it when the need arises. But some work of Leather's in India and Alway's on the great plains of North America throw doubt on this view, and would suggest that only the layer traversed by roots, say, down to a depth of 6ft., can supply water to the crop; the water movements from the deeper layers due to capillarity being too slow to be of much effect in the maintenance of the plant. The evidence on either side is far from being conclusive and more experiment is very desirable.

It would also be valuable to know how far evaporation from the bare soil can be checked by suitable screens or hedges that will break the sweep of the wind across the land. In England hedges have always been looked at from the point of view of shelter for stock; we find them most developed in the grazing districts of the west, while bare open fields prevail in the east and south. Yet the enormous value of a wind-screen to vegetation can be readily observed, and the market gardeners both in England and the still dryer districts of the south of France make great use of them. Lastly, we must have more knowledge about the relation between transpiration-water and growth: we do not know if the high ratios we have spoken of hold for all

plants. Xerophytic plants are supposed to be possessed of protective devices to reduce loss of water : Are they merely effective in preserving the plant from destruction during the fierce insolation and drying it receives ? and do they enable a plant to make more growth on a given amount of water ? Wheat, for example, puts on its glaucous waxy bloom under dry conditions : Is this really accompanied by a lower rate of transpiration per unit surface of leaf ? and is it more than defensive, connoting a better utilisation of the water the plant evaporates ?

The cultivation of these soils with a minimum rainfall necessitates varieties of plants making a large ratio of dry matter to water transpired and also with a high ratio between the useful and non-useful parts of the plant. Mr. Beaven has shown that the difference in the yields of various barleys under similar conditions in England are due to differences in their migration factors : and the same amount of dry matter is produced by all, but some will convert 50 per cent. and others only 45 per cent. into grain. This migration ratio, as may be seen by the relation between corn and straw on the plots at Rothamsted, is greatly affected by season ; nevertheless Mr. Beaven's work indicates that under parallel conditions it is a congenital characteristic of the variety and therefore, one that can be raised by the efforts of the plant-breeder. The needs of dry-land-farming call for special attention on the part of the breeder to these two ratios of transpiration and migration.

#### IRRIGATION LANDS.

Closely linked up with the problems of dry-land-farming are those which arise in arid climates from the use of irrigation water on land which is either impregnated with alkaline salts to begin with or develops such a condition after irrigation has been practised for some time. The history of irrigation farming is full of disappointments due to the rise of salts from the subsoil and the subsequent sterility of the land ; but the conditions are fully understood, and there is no longer any excuse for the disasters which have overtaken the pioneers of irrigation in almost every country. Sterility may arise from two causes--overmuch water which brings the water-table so close to the surface that the plants' roots may be asphyxiated, or the accumulation by evaporation of the soluble salts in the surface layer until plants refuse to grow. The annual cutting off of the cotton crop in Egypt as the water-table rises with the advance of the Nile flood affords a good example of asphyxiation, but in the neighborhood of irrigation canals we also find many examples of sterility due both to the high water-table and an accompanying rise of salts. The governing principle is that drainage must accompany irrigation. Even if free from salts at the outset the land must accumulate them by the mere evaporation of natural waters, and they will rise to the surface where they exert their worst effect upon vegetation, unless from time to time there is actual washing through the soil and removal of the water charged with salt.

Without drainage the greater the quantity of water used the greater the eventual damage to the soil, for thereby the subsoil water-table carrying the salts is lifted nearer the surface. With a properly designed irrigation system the danger of salting ought not to occur; there are, however, many tracts of land where the supply of water is too limited to justify an expensive scheme of irrigation channels with corresponding drainage ditches at a lower level. Take the case of a single farmer with some water from an artesian well at his disposal, with perhaps little rainfall, with land subject to alkali, and no considerable natural fall for drainage. If he merely grades the land and waters it, sterility rapidly sets in; the only possibility appears to be to take a comparatively limited area and to cut out drainage ditches or tile drains 4ft. or 5ft. below the surface, even if they have to be led into a merely local hollow that can be abandoned to salt. The bed thus established must then be watered at any cost until there is a flow in the drains, after which the surface is immediately cultivated and the crop sown. There should be no further application of water until the crop covers the land, the use of water must be kept to a minimum, and by the ordinary methods of dry cultivation evaporation must be allowed only through the crop, not merely to save water but to prevent any rise of salt. With a loose surface and wind-breaks to minimise evaporation it has thus proved possible to grow valuable crops even on dangerously alkaline land. Superphosphate and sulphate of ammonia have proved to be useful fertilisers under these conditions; both tend to prevent the reaction of the soil becoming alkaline, and the calcium salts of the superphosphate minimise the injurious effects of the sodium salts that naturally accumulate in the land. On the other hand, nitrate of soda is a dangerous fertiliser. Attempts have been made to reduce the salts in the land by the growth of certain crops which take up a large proportion of mineral matter, but I have not been able to ascertain that much good can be thus effected. Sugar-beet and mangolds do appreciably reduce the salt content, but are hardly valuable enough to pay for such special cultivation and the limited irrigation water; the best thing appears to be to grow salt-bush on the non-irrigated margin of such areas, if only to prevent the efflorescent salts from blowing on to the cultivated portion.

#### LAND RECLAMATION IN EUROPE.

Let us now turn to the problem of land reclamation as it occurs in North-Western Europe. There are two main types of land that have hitherto been left waste, the peaty and the sandy areas. Of the peaty areas we can distinguish again between the low-lying moors bordering the lower courses of the great rivers; for example, in England, near the mouth of the Trent, and the upland peat-bogs of which Ireland furnishes so many examples. They have these features in common—an excess of water, a deficiency of mineral salts, and, particularly in the upland bogs, a strongly acid reaction; but they possess

great potential wealth in their richness in nitrogenous organic matter. It is in Germany and Holland that the methods of bringing into cultivation these moors have been most completely worked out ; in Germany, for example, it is estimated that there are about 5,000,000 acres of moorland, of which about 10 per cent. are now under cultivation. This reclamation process must begin by drainage, which may be carried out by open ditches, but is most satisfactorily effected by pipes, despite the greater cost. The water-table must be kept some 3ft. below the surface. In districts which afford a market for peat, as, for example, on the Teufelsmoor, near Bremen, the reclamation often begins by cutting out the peat, the lower layer of firm peat being won, dried, and sold for fuel. The upper spongy peat can be used for litter, but some part, at least, must be thrown back. Where the burning peat is thus extracted the excavation is in places pushed further until the underlying sand is reached, and enough of this is dug to spread over the reclaimed area to a depth of 4in. or 5in., and mixed by cultivation with the spongy peat. Even when the peat is not removed, pits are often made in order to sand the land, so great an improvement does it effect in the character of the crops. However, sanding is not possible everywhere, and there are great areas under cultivation where the reclamation begins with drainage, followed by the cultivation of the immediate surface without either sanding or the removal of the burning peat, which indeed are impossible over large areas, but are carried out by the owners of small farms little by little. Special tools are required ; certain forms of disc-ploughs and harrows give the best results ; heavy tools for large scale cultivation by steam or electricity are furnished with broad roller-like wheels ; even the horses must wear broad wooden shoes.

The next stage is the manuring, and it has only been the development of the artificial fertiliser industry during the last half-century that has rendered the cultivation of this type of land possible. On the alluvial moors where the ground water has always been alkaline, the peat is rich in calcium, and no treatment with lime and marl is necessary (the English fens afford an example of this type of soil), but on the true peat-bogs (Hochmoor) of Germany the manuring must begin with a good dressing of burnt lime, or, better, of marl or ground chalk. For meadows and pastures 2 tons per acre of lime, or twice as much of carbonate of lime, should be applied ; the amounts may be halved for arable land. This must be followed by about 5cwts. to 8cwts. per acre of basic slag and an equal amount of kainit, which applications should be renewed in the second year, but then diminished in accord with the cropping. However, some phosphoric acid and potash salts must be continuously supplied, with occasional dressings of lime or chalk on the acid peaty areas. These latter also require in their earlier years nitrogenous manures, for the peat is slow to yield up the nitrogen it contains. The fertilisers should be nitrate of soda or lime, never sulphate of ammonia. The whole success of the reclamation depends on the use of these manures, as the peat in a state of nature is almost devoid of

both phosphoric acid and potash ; on the acid peats, again, normal growth is only possible after a neutral reaction has been attained by the use of lime or marl. With this manuring it is found to be easy to establish a good meadow herbage in a very short space of time ; it is not even necessary to get rid of the surface vegetation of *Erica* and other heath and bog plants. The manure is put on, and the surface is worked continuously with disc-harrows and rollers, but never deeply ; a seed-mixture containing chiefly red, white, and Alsike clovers, *Lotus uliginosus*, rye-grass, Timothy, and cocksfoot, is sown in the spring and soon succeeds in choking the native vegetation.

It is impossible to say what is the cost of the reclamation of moorland in this fashion ; the big expense is the drainage and the construction of roads, both of which are entirely determined by local conditions. But of the value of the process when accomplished there can be no doubt. I have seen a case quoted from the *Ostfriesische Zeitung*, where a piece of moor bought for 75*l.* was reclaimed and sold for 900*l.* ; and, best test of all, one may see in places like the Teufelsmoor, near Bremen, families living in comfort on 30 to 40 acres of what was once merely wild moor with no productive value.

Of even greater interest in England is the reclamation of heath-land, which has of late years been proceeding apace in Germany. In this category we may include all land which owes its infertility to the coarse grade and low water-retaining power of the particles of which the soil is composed, the soil being at the same time as a rule devoid of carbonate of lime, and covered in consequence with heather and similar calcifuge plants. In England there exist extensive tracts of uncultivated land of this character in close proximity to the considerable populations, but the process of reclaiming such land for agriculture seems to have come to an abrupt conclusion somewhere about 1850, when the developing industries of the country began to offer so much greater returns for capital than agriculture. That land of the kind can be cultivated with success is evident from the mere fact that everywhere prosperous farms may be seen bordering the wastes, possessing soils that are essentially identical with those of the wastes. These were brought under cultivation when labor was cheaper, often without calculation of the cost, because the work was done piecemeal at times when the men would otherwise have been idle. Were any strict account to be framed, the reclamation probably did not pay its way for many years, and it has only become possible again because of modern advances in science and machinery. As examples of this type of land, I may instance the Bagshot Sands on which, in north Surrey, in Berkshire and Hampshire, and again in its southern development in the New Forest, lie so many thousands of acres of uncultivated heath. No systematic reclamation has taken place, but everywhere farms have been carved out on this formation often by the industry of squatters, and within reach of London the vast supplies of town manure which used to be available have converted some of it into fertile land. The crystallisation of common rights into charters for public playgrounds, its growing

appreciation for residential purposes, will now always stand in the way of the utilisation of most of the Bagshot Sands for agriculture, but further afield there are many areas of similar character. The Lower Greensand is, perhaps, equally discounted by its residential value, but on the Tertiaries of Dorset, the Crag and Glacial Sands of Suffolk and Norfolk—the brack, the Bunter Beds of the Midlands, lie many expanses of waste that are convertible into farming land, just as Lincoln Heath and much of the beautifully farmed land of Cheshire have been gained for agriculture within the past century. Equally possible is an attack upon the sandy areas, warrens or links, behind the sand dunes on many parts of the English, and especially the Welsh coasts; not all of them are wanted for golf, and many can be fitted for market gardening. Of old the only way of dealing with such land was merely to clear it, burn the rubbish, and start upon the ordinary routine of cultivation; but for a long time on such a system the crops will hardly pay their way from year to year, and the permanent deficiencies of the soil in lime and mineral salts remain unrepaired. In Cheshire the enormous value of marl and bones in such a connection was early recognised; it has been the later discovery of the potash salts that renders reclamation a commercial proposition to-day. The method that is now followed is to begin by clearing the land of shrubs, burning off the roughest of the vegetation, and turning over a shallow layer in the summer, leaving the heathery sod to the killing and disintegrating action of sun and frost until the following spring. The manure is then put on—lime or ground chalk or marl as before, basic slag and kainit, and the sod is worked down to a rough seed bed on which lupins are sown, to be ploughed in when they reach their flowering stage. The growth of the lupins makes the land, they supply humus to bind the sand together and retain moisture, they draw nitrogen from the atmosphere, and with the phosphoric acid and potash form a complete manure for succeeding crops. Sometimes a second crop of lupins is ploughed in, but usually the land is put immediately to an ordinary rotation of rye, oats, potatoes, and clover. When the heath-land is divided among small tenants in an unreclaimed state, cropping often begins without the lupins, the necessary nitrogen being imported by nitrate of soda, but for years the land shows inferior results. Only the tenant can rarely afford to lose the year the lupin crop involves, and so great is the demand for land in Germany that the State finds it preferable to let the tenant reclaim than to reclaim for him, and charge him as rent the cost of the more thorough process. And now as to the finance of the operation: the reclaiming down to the ploughing in of the lupin crop costs from 5*l.* to 6*l.* an acre, the bare heath costs from 5*l.* to 7*l.* an acre, the reclaimed land after a few years' cultivation would sell at 20*l.* to 30*l.* an acre. Meantime the State has probably made a free grant for drainage, looking to get some interest back in increased taxation; the local authority has also made roads for which the increased rating due to a new agricultural community must be the only return. It is a long-sighted policy

which will only find its full justification after many years when the loans have all been paid off and the State has gained a well-established addition to its agricultural land and its productive population. In comparing English with German conditions there are certain differences to be taken into account—in the first place, the work of reclamation will be dearer in England, because of the higher price of labor, then the land will not be so valuable when won because the higher scale of prices for agricultural products enhances the price of land in Germany. Next, I doubt, in view of the great industrial demand for men in England, if we have the men available who will bring to the land the skill and power of drudgery that I saw being put into these German holdings of 30 to 40 acres in their earlier years of low productivity. Moreover, in Germany these heaths are generally bordered by forests, in which the small holder gets occupation for part of the year while his wife and children keep the farm going. For this, if for no other reason, afforestation and land reclamation and settlement should go on together. But, despite these drawbacks, I am still of opinion that the reclamation of such heath-lands is a sound commercial venture in England, either for a landowner who is thinking of a future rather than of a present return on his capital, or for the State or other public body, wherever the waste land can be acquired for less than 5*l.* an acre. The capitalised value of its present rental rarely approaches that figure, but the barrenest heath is apt to develop the potentialities of a gold mine when purchase by the State comes in question. The map of England is so written over in detail with boundaries and rights and prescriptions that the path of the would-be reclaimer, who must work on a large scale if he is to work cheaply, can only be slow and devious. There are other possibilities of winning agricultural land even in England, from the slob land and estuaries, from the clays nowadays too heavy for cultivation; but the problems they present are rather those of engineering than of agricultural science. What I should like, in conclusion, once more to emphasise is, that the reclamation of heath and peat land, of which I have been speaking—reclamation that in the past could only be imperfectly effected at a great and possibly unremunerative expense of human labor—has now become feasible through the applications of science—the knowledge of the functions of fertilisers, the industrial developments which have given us basic slag and potash salts, the knowledge of the fertility that can be gained by the growth of leguminous plants. From beginning to end the process of reclamation of moor and heath, as we see in progress in North-Western Europe, is stamped as the product of science and investigation.

## A SELECT LIST OF FRUIT TREES, GRAPE VINES, AND BUSH FRUITS.

---

WITH BRIEF HINTS ON PLANTING.

---

Compiled by GEORGE QUINN, Horticultural Instructor.  
1914.

To secure the best results, land intended for planting should be thoroughly prepared some time beforehand. If it be virgin scrub or forest land a crop of cereals or vegetables may be taken off prior to fallowing it up in readiness for the fruit trees. In all cases the whole of the surface should be broken, and, unless the sub-layers are open and gravelly, the subsoil must be deeply stirred, but not brought to the surface more than can be avoided.

Lands with a stiff clay subsoil and situate in localities receiving more than about 25in. of rain annually, or to which irrigation water is to be applied regularly, will not give permanently good results unless provision be made for under drainage. This may be secured by pipe drains, slabs, or stones laid in by well-known methods.

In large areas the soil is broken by means of a subsoil plough being drawn along in each furrow made by an ordinary turning plough. This work is best performed in autumn or spring, when the surface is sufficiently wet to permit of a deep furrow being cut by the turning plough and the subsoil is not wet enough to pug and make the draught of the second plough too heavy. On small areas this work is usually done by means of the spade and pick, or the subsoil may be fractured by the use of explosives inserted in each spot where a tree is to be set. The digging of large deep holes is not recommended, more particularly into stiff clay subsoils. This preparatory work should in all cases loosen the soil to a depth of from 12in. to 18in., thus enabling the roots to strike freely down to a depth not rapidly affected by heat or cold.

In selecting positions for fruit trees, gentle slopes are always preferable to level land, excepting the soil be unusually deep and well drained naturally. The olive, almond, fig, grape vine, and pear are most suited to dry soils, though singularly enough the pear will thrive in land which would be too wet for any other kind of cultivated fruit trees. The quince and plum may be said to come next in resistance to saturation. The cherry, loquat, walnut, and persimmon delight in a deep, cool, moist soil, rich in organic matter,

whilst the peach and apricot prefer light, deep, clay or sandy loams of a well-drained character. Citrus trees do not prove profitable, excepting when planted on deep, loose, moisture-holding alluvials or sandy loams perfectly under-drained, naturally or by artificial means.

All fruit plantations must be secured against rabbits and other vermin by means of wire netting or other close fencing. Shelter from rough or cold winds is essential in all cases. Wherever the contour of the surrounding land is not sufficiently protective a belt of forest trees should be planted along the sides of the orchard open to prevailing winds. The nearest row should not stand less than 50ft. from the first row of fruit trees, unless the soil be very deep and the moisture abundant. Of high trees pines are preferable to gum trees—the Remarkable pine in wet districts and the Aleppo pine in those receiving less than 25in. of rain per annum. These trees should be set from 6ft. to 12ft. apart in alternating rows, and receive surface tillage during the first few years. For smaller areas hedges of carob, tagosaste, tamarisk, or kaffir apple, or double rows of almond or loquat, or in some instances fig trees may be used to advantage. In still smaller plots fences of high palings or galvanized iron afford good shelter, and do not remove moisture or plant food from the land.

Trees are usually set over the surface of the land in figures representing squares or equilateral triangles. For commercial purposes the former is recommended as lending itself to convenient cross-working of the land for all time. The distances apart to plant the trees will depend on the kinds of fruits to be grown, as well as the richness of soil and supply of moisture available to them.

Under irrigation greater distances are needed, and 22ft. apart on the square is usually necessary for practically all sorts of standard trees. In the ordinary soils of the non-irrigated or only slightly watered areas about 20ft. squares usually suffice. At the former distance 90, and at the latter 108 trees can be placed upon an acre of land. In small home gardens cultivated by hand labor the trees may receive more minute attention individually, and consequently the distances may range from 16ft. apart upwards.

The best time to plant deciduous trees and grape vines in this climate is during early winter, just after the first soaking rains have fallen, and the soil is yet warm. They will then send out fresh fibres to repair their broken root systems, even whilst the leaves fall and the tops are going to rest. Before planting the trees the broken roots should be cut back to healthy tissues, and all fibrous roots which are shrivelled may be clipped off as well. The roots and stem should be inserted into the soil about the depth they formerly stood in the nursery bed, as indicated by the soil marks and peculiarly discolored bark. If any animal manure is added to the soil about the roots it should be well decomposed, and only bonedust, or basic slag, amongst

the purely phosphatic fertilities are safe. A little blood manure or sulphate of ammonia may be used, but the latter only very sparingly. As a suggestion, about 1lb. of the bonedust, blood manure, or slag, or 4ozs. of the sulphate of ammonia may be applied if well mixed with the soil. When farmyard manures are used only three or four good shovelfuls are needed. The soil should be firmly trodden down between and upon the roots at the planting time, and if it be dry an irrigation should follow immediately. Deciduous trees and vines should not be pruned back until after planting is finished, and then there is no hurry for a few weeks. Each tree should have a stake driven down in its position before it is planted. This is not to support the tree, but rather to indicate the spot it occupies, and protect it from knocks during the conduct of tillage operations for the first couple of years.

Citrus trees usually respond best when set out into the orchard in early spring, just as they give evidence of returning activity of vegetation. There is not the same danger of the first tender growth being injured by frost as is the case when moved late in autumn and excited into tender growth, as they invariably are by the transplanting. They need cutting back severely immediately after the transplanting takes place if the root system of the tree has been mutilated or dried up. As this pruning usually exposes the bark to the sun, a thin covering of straw wrapped loosely around each stem proves an advantage.

Beginners are expressly advised to avoid very large nursery trees, but rather to choose those of one season's growth only from the bud or graft, and that consisting of moderately large well-ripened short-jointed wood carrying well-defined buds.

In deciding which varieties to plant the commercial fruitgrower must be guided by the market available for his produce. In consequence, he usually limits his efforts to the production of a few well-defined kinds. This is more particularly emphasised amongst the growers of export kinds, as well as with those producing dried fruits. The grower for a local market may with safety take a wider range, whilst the home gardener's fancy is only circumscribed by the limits placed upon him by the stresses of soil or climate. If the locality affords no opportunity for noting the suitability of different kinds of fruits or varieties of the same, the planter would do well to set out a greater number of varieties and watch their behaviour. The following, however, may afford some guide to a selection :—

#### APPLES.

*Exporting* (best).—Cleopatra, Jonathan, Dunn's Seedling ; (second best) London Pippin, Worcestershire Pearmain, Esopus Spitzenburg, Dumelow's Seedling, Rome Beauty, Statesman, Strawberry Pippin, Stone Pippin, Gascoyne's Scarlet, Reinette de Canada.

*New Sorts Worthy of Trial*.—King David, Delicious, Stayman Winesap.

*For Late Keeping.*—Stone Pippin, Rokewood, Cleopatra, Strawberry Pippin, Nickajack, Shockley, Rome Beauty, Pioneer, Crofton Pearmain, Granny Smith, Sturmer Pippin.

*Early Ripening for Local Use.*—Margaret, Gladstone, Red Astrachan, Irish Peach, Beauty of Bath, Gravenstein, William's Favorite, Ribston Pippin, Twenty Ounce, Lord Nelson.

Of the leading varieties given above Cleopatra and Dunn's, owing to susceptibility to various diseases, are most suitable for planting in warm parts of the State with a rainfall not exceeding 27in. per annum, whilst Jonathan, Rome Beauty, London Pippin, Stone Pippin, Worcestershire Pearmain, Delicious, Sturmer, Statesman, and Stayman Winesap should be planted in the cooler and wetter localities.

#### PEARS.

*Exporting (best).*—Glou Morceau, Beurre Bosc, Joséphine de Malines, Winter Nelis; (second best) Madam Cole, Broom Park, Beurre Diel, Beurre Clairgeau, Durondeau, L'Inconnue, Vicar of Winkfield.

*Worthy of Trial.*—Packham's Triumph, Doyenné du Comice, Keiffer's Hybrid.

*For Late Keeping.*—Josephine de Malines, Madame Cole, Broom Park, Harrington's Victoria, Uvedale's St. Germain, Swan Egg, Black Achan.

*Early Ripening for Local Use.*—Citron de Carmes, Jargonelle, William's Bon Chrétien, Clapp's Favorite, Wilder, Howell, Beurre Capiaumont, Passans de Portugal, Beurre Giffard.

*Most Suitable for Canning.*—William's Bon Chrétien.

*Most Suitable for Drying.*—William's Bon Chrétien, Passans de Portugal, Poire de Berriays.

#### PEACHES.

*In Order of Ripening from early December till April.*—Sneed, High's Early Canada, Ulati, Triumph, Hale's Early, Ruby Red, Wiggins, Peregrine, Louis Groquet, Mountain Rose, Early Crawford, Muir, Elberta, Lovell, Red Shanghai, Belle of Georgia, Finlayson's Seedling, Lady Palmerston, Salwey, Riverside Red Italian Clingstone, Pullar's Clingstone, Levis Clingstone (Ruby Red and Red Shanghai are clingstones also).

*Best for Drying and Canning (freestones).*—Early Crawford, Elberta, Muir, Lovell, Lady Palmerston, Salwey; (clingstones) Pullar's, Riverside Red Italian, Levis Cling.

#### NECTARINES.

*In Order of Ripening from December to March.*—Dr. Chisholm, Rivers Cardinal, Early Rivers, Goldmine, New Boy, Zeelandia, Stanwick.

*Suitable for Drying.*—Goldmine (New Boy and Zeelandia are also worthy of trial).

#### APRICOTS.

*In Order of Ripening.*—Mrs. Hart, Newcastle Early, Oullin's Early, Riverside, Royal, Kaisha, Moor Park, Robin's Imperial.

*For Drying and Canning.*—Moor Park.

#### PLUMS (EUROPEAN).

*Blue or Black.*—Angelina Burdett, Fellemberg, Kirke, Splendor, President, Diamond, Old French Prune, Evan's Early.

*Red and Purple.*—Early Orleans, Giant Prune, Grand Duke, Prune D'Agen, Monarch, Purple Gage, Robe de Sargent.

*Yellow and Green.*—Coe's Golden Drop, Greengage, Jefferson, Monfries' Golden Drop, Reine Claude de Bavay.

*Best for Drying.*—Fellemberg, Splendor, President, Old French Prune, Prune D'Agen, Robe de Sargent, Coe's Golden Drop, Jefferson (Angelina Burdett and Greengage also dry well).

*Best for Canning.*—Coe's Golden Drop, Jefferson, Greengage, Reine Claude de Bavay.

#### DAMSONS.

Shropshire, Vermont, Old English.

#### JAPANESE HYBRID PLUMS.

Burbank, Climax, Satsuma, Sultan, Federation, Wickson, Wright's Early, Formosa Rubio, Ballena.

Although possessing excellent flavors as dessert fruits, extensive planting of these Japanese plums is not advocated.

#### CHERRIES.

Early Purple Guigne, Early Lyons, Burgdorf's Seedling, Biggareau Napoleon, Florence, St. Margarets.

#### FIGS.

White Genoa, Black Ischia, White Adriatic, Castle Kennedy.

#### ALMONDS.

*Papershells.*—Hatch's Nonpareil, Ne Plus Ultra, I.X.L., Peerless. *Soft-shells.*—White Nonpareil, Brandis. The first three are American varieties not liable to "gumming," the last three, and particularly the Brandis, are very subject to this defect. Peerless and Hatch's Nonpareil are of a very drooping, spreading habit. Brandis is tall and upright.

#### ORANGES (SWEET).

*Navels.*—Washington, Thompson's Improved, Navelencia, Golden Nugget, Buckeye.

*Non-Navels.*—Ruby Blood, Joppa, Mediterranean Sweet, Rio, St. Michael, Queen, Siletta, Nonpareil, Valencia Late, Parker's Seedling.

*Mandarins*.—Dancy's Tangierine, Beauty of Glen Retreat, Emperor, Japanese Seedless (*Oonshiu*), Scarlet, Nobilis, Fewtrill's Shipper, Jacob's Improved. The two last-named are sweet orange crosses with Mandarins.

#### LEMONS.

Lisbon, Eureka, Variegated.

#### POMELO, OR GRAPE FRUIT.

Marsh's Seedless, Triumph, Improved, Common.

#### CITRUS (FOR PRESERVING).

Poorman, Flat Seville, Common Seville, Bengal Citron. *Kumquats* Round and Oval.

#### CITRUS (FOR BEVERAGES).

*Limes*.—East Indian (dark-yellow skin), Tahiti (light skin).

#### QUINCES.

Champion, Smyrna, Pineapple, Reas' Mammoth.

#### GRAPE VINES (TABLE GRAPES).

*Blacks*.—Black Hamburg, Black Prince, Grand Turk, Trentham Black, Madresfield Court Muscat, Mrs. Pince's Muscat, Muscat Hamburg, Wortley Hall, Ullaide, Black Malaga.

*Reds*.—Red Prince, Red Malaga, Red Frontignan, Wood's Red Muscat, Lady's Finger.

*Whites*.—Crystal, Belas Blanco, Doradillo, Early Green, Muscat Gordo Blanco, Sweetwater, Duke of Buccleuch, Waltham Cross, Santa Paula, Temperano, Raisin des Dames, Buckland Sweetwater, Pedro Ximines, Daira.

#### STRAWBERRIES.

Melba, Sir Joseph Paxton, La Marguerite, Sunbeam, Royal Sovereign.

#### GOOSEBERRIES.

*Reds*.—Billy Dean, Crown Bob, Roaring Lion.

*Greens and Yellows*.—Heart of Oak, Leveller, White Lion.

#### RASPBERRIES.

Northumberland Fillbasket, Fastolf, Laxton's Superlative, Thornless Fillbasket.

#### OLIVES.

Verdale, Blanquette, Bouquettier, Gros Rodoneau, Hardy's Mammoth. The last-named is a large fruit, suitable for pickling.

#### JAPANESE PERSIMMON, OR DATE PLUM.

Heycheya, Dai Dai Maru, Kurokumo, Yemon, Seedless.

## ADVISORY BOARD OF AGRICULTURE.

---

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, August 12th. The Chairman (Mr. G. R. Laffer, M.P.) presided, and there were also present the Director of Agriculture (Professor Perkins), the Principal of Roseworthy College (Mr. W. J. Colebatch), Messrs. F. Coleman (Vice-Chairman), C. J. Tuckwell, C. E. Birks, A. M. Dawkins, J. Miller, and G. G. Nicholls (Secretary).

*Appointment of New Member of Board.*—The Chairman, at the commencement of the meeting, read a letter from the Minister of Agriculture (Hon. T. Pascoe, M.L.C.) intimating that he had appointed the Principal of the Agricultural College (Mr. W. J. Colebatch) to be a member of the Advisory Board of Agriculture.

*Hay and Chaff Act.*—Relating to a request from the Lyndoch Branch that the Hay and Chaff Act might be amended to permit of the sale and purchase of half-bags of chaff, a reply was received from the Minister of Agriculture to the effect that it was not proposed to interfere with the Act this year. Mr. Dawkins said several chaff merchants had complained bitterly to him respecting their difficulties in connection with the bags. Bags often were returned to them in pieces, and a great many were totally lost, involving them in considerable financial loss. The merchants would like to sell the bags with the chaff, and then, if desired, they could buy them back afterwards.

*Forests near Williamstown.*—A communication from the Commissioner of Crown Lands contained a report from the Conservator of Forests (Mr. W. Gill) relative to the alleged destruction and the preservation of timber in the Williamstown district. The document stated—"The question of the lands referred to has been under the full consideration of several Governments during the last few years, and as suitable opportunities have occurred the lands have been dedicated as forest reserves at my recommendation. Operations on some of these lands are now in progress." An accompanying memorandum by the Commissioner was to the effect that no official information had been received regarding trees having been cut down since the services of the inspector were dispensed with. After discussion the Director of Agriculture, Messrs. Laffer, Coleman, and Dawkins were appointed a committee to inspect the district and ascertain the exact state of affairs. Mr. Coleman emphasized that his idea in having brought the matter up in the first instance was to obtain adequate protection for the old, the growing, and the prospective natural timber on the miscellaneous lease lands.

*Compulsory Sheep-dipping.*—At the Conference of the South-Eastern Branches of the Bureau at Penola in 1913, the Naracoorte Branch sought to have action taken in the direction of securing the compulsory dipping of sheep throughout the State. Advice was tendered, however, that it should go more thoroughly into the subject, and, acting on that suggestion, 37 Branches in the South-East and the districts south of Adelaide were communicated with. A report from the Naracoorte Branch was now received stating that of the Branches which had replied, 16 had supported the proposals for compulsory dipping, six had intimated that they were not interested, and only three had stated that they were satisfied with the present Act. The Branch, therefore, strongly urged that the Government should be requested to take the necessary steps to bring about compulsory dipping. It was resolved that Professor Perkins, Mr. Colebatch, the Chief Inspector of Stock, and Mr. C. E. Birks should form a committee to deal with the matter and report to the Board.

*Shoot Scorchers.*—A resolution was received from the Carrow Branch requesting the Advisory Board to use its influence to induce the Government to offer a substantial bonus for the invention of an effective machine for scorching mallee shoots, the machines to be judged at a field trial, and their relative merits to be determined according to their efficiency, the cost of the machines, and the cost of treatment. It was decided to defer the consideration of the request until after the Conference of the Pinnaroo Branches, at which it was suggested inquiries should be made concerning the requirements of a machine such as that referred to.

*Experimental Farm Wanted.*—From the Conference of Eyre's Peninsula Branches the following resolution was received, viz. :—" That this Conference urges upon the Government, through the Advisory Board, the need for the immediate establishment of an experimental farm in this extensive district in a central position." Mr. Coleman said experimental farms undoubtedly served a very useful purpose, but he would like to see established a farm to be worked on purely practical commercial lines. Professor Perkins pointed out that the difficulty—or, at least, one among others—in the way of the adoption of that course would be to secure a thoroughly efficient manager. A really good man would require to be paid a pretty high salary, otherwise he would prefer to farm on his own account, as he would be able to do better financially. In view of the fact that it had been definitely decided to have at least one experimental farm, and possibly two might be organised in that vast district, he suggested that Mr. Coleman should keep his proposal in mind, and mention it again later when the question of selecting a site or sites was under consideration. So soon as possible after the September Congress, at the instance of the Minister, he was going to visit the district in connection with the matter. The resolution was sent on to the Minister.

*Fencing Material Desired.*—From the Coomandook Branch there was a resolution to the effect that the Advisory Board be asked to suggest that the Government provide fencing material for boundary fences on newly-opened country on the same terms as district councils provide wire netting. Mr. Colebatch pointed out that it was most desirable for the farmers, wherever possible, to keep sheep; but in the mallee country that could not be done until suitable fences were erected. He recommended that if it were at all feasible something should be done in the desired direction. At the instance of Mr. Coleman it was determined to send the request on to the Minister, strongly advising compliance therewith.

*New Branches.*—Approval was given to the formation of Branches at the undermentioned places, with the following gentlemen as members:—Long Flat—J. G. Forster, J. J. Doyle, C. Mugford, P. V. Ryan, E. T. Forster, F. G. Fiebelt, P. E. Opie, H. S. Mann, A. E. Forster, C. H. Say, A. L. Ive, E. S. Squire, D. Burdon, F. Sleep, J. T. Rouse, L. H. Fielke, J. G. Schubert, W. Bateson; Kingston-on-Murray—C. J. Holmes, E. W. Chaston, J. Wetherall, S. Pope, W. C. Pope, C. E. Setterberg, M. Merritt, P. S. Stubbs, H. Holmes, S. Saunders, J. Aird, F. Holmes, W. Wetherall, J. E. Harrington; Milang—J. Cheriton, M. Charles, W. P. Dunk, A. Ferguson, F. Gardener, T. H. Goldsworthy, D. M. Goldsworthy, T. Higginson, F. Kruse, sen., A. D. Matheson, E. J. McLean, M. McBain, E. W. Ness, L. Pavy, G. Perry, W. Perry, J. Rust, W. E. Richards, A. H. Summer, A. Saltmarsh, Walter Saltmarsh, William Saltmarsh, G. Tee, W. J. Vercoe, J. C. Whitfield, J. M. Yelland, W. S. Yelland, H. Overall, A. Davidson.

*Life Members.*—The following life members were approved:—Messrs. James Darley, Narridy Branch; T. A. Thomas, Balaklava Branch; and H. Bawden and John Hill, Maitland Branch.

*New Members.*—Carrow—D. C. Burt, F. T. Burt, G. Barranger; Salisbury—A. O. Coker, H. Hedde, J. Howe; Coorabie—E. G. Squire, A. Gregory, W. A. Wetherill; Waikerie—F. Lewis, J. Parkes, I. Isaacson, W. Crooks; Mount Remarkable—M. J. Murphy; Kadina—J. A. Cowley; Keith—J. Barkley, H. Burns; Narrung—S. M. Hunt, T. W. Smith; Orroroo—F. P. Keats, M. J. Neylan, F. J. Bills; Crystal Brook—C. Coffrey, C. C. Buttfeld, W. J. Spackman, Rev. J. McIntosh, R. Townsend, E. H. Maidment; Port Elliot—W. Henderson; Gumeracha—W. F. Nickels, L. Jamieson; Koppio—R. Schultz; Blackwood—W. Turner; Claypan Bore—D. Small; Mount Compass—A. Horner; Penong—A. Neilson, O. J. Murphy; Hartley—G. Camac, F. Hassam; Wilmington—T. D. Peck; Spalding—A. W. Holland, L. Judell, W. Fudge, A. F. Low; Nadda—O. Grave, W. F. Bothe, H. E. Phillis, W. Meadows; Laura—J. Sandow, G. Wakeham, F. T. Hughes; Uraidla and Summertown—A. Hunt, S. Cornish, I. Little; Clarendon—A. M. Taylor; Goode—F. T. Morcombe, S. Burner, D. H. Stephenson, A. M.

Stephenson ; Northfield—J. A. Warden ; Orroroo—C. P. Wake ; Renmark—A. J. Barge, E. Pitt ; Monteith—J. Denman, S. J. E. Weatherall, E. B. T. Inglis, F. D. M. South ; Mount Bryan—H. R. Hooper, E. Wedding ; Wynarka—W. Langhams ; Borrika—R. E. Wilhelm ; Moonta—J. Thomas, L. Williams, J. Goldsworthy, T. Polgreen ; Salt Creek—J. Rivetts ; Geranium—H. Perrin, A. J. T. Besley ; Butler—S. L. Butler ; Yadnarie—W. J. Johnson ; Clare—L. Longbottom ; Maitland—O. Jones ; Elbow Hill—A. O. Dawkins, F. Chilman, H. B. Phillips ; Glencoe—J. Riddoch, J. Barry ; Yabmana—C. Harvey, L. Crittenden, A. Robertson ; Coomandook—S. N. Patterson, A. S. C. Badenock, F. E. Ballard, R. Upton, L. G. Brown, H. S. Hughes, C. R. Williams, J. C. Guy, J. Guy, H. Guy, V. Tueber, H. March, W. March, F. March, J. Eschener, L. Eschener ; Wirrega—H. T. Exton, W. M. Grandy ; Miltalie—J. C. Busch ; Hartley—A. Hart ; Carrow—R. Kemp, J.P., F. Larkin ; Iron Bank—B. Jones, R. Jones ; Georgetown—G. Wells ; Naracoorte—R. P. Haynes, R. R. Stinson, J. H. Coad ; Appila-Yarrowie—R. Wilson, R. L. Lines ; Narridy—J. Liddle ; Wepowie—H. W. Noske ; Amyton—W. Baumgartel, A. G. ## POULTRY NOTES.

By D. F. LAURIE, Government Poultry Expert and Lecturer.

### WORTHY OF YOUR CLOSE ATTENTION.

#### Markets for Poultry Products.

Producers should not be discouraged at the prospects of a temporary period of low prices for eggs. This, I anticipated, would result in the absence of an oversea export trade. Years ago I advocated oversea export, and trial shipments demonstrated excellent possibilities. Events did not tend to a continuance of this wise course. Poultry breeders were lulled into a sense of security of profitable prices in the local markets, despite the fact that in every State the progress of the poultry industry has been most marked. There must be pioneers in all movements tending for progress and betterment of conditions. The trouble is that the average poultry breeder has been content to let others shoulder the general responsibilities, and things have remained "in statu quo." Trade announcements which recently appeared in the press are tantamount to admissions that the local markets are insufficient. It behoves those immediately concerned to put their shoulder to the wheel with a view of having some more definite say in the matter of markets. Great Britain is our natural and national market, and it is an enormous one, capable of absorbing all the surplus poultry products we are ever likely to produce. The present imports into England, excluding over £5,000,000 for eggs alone from Ireland, exceed 10 millions sterling annually. Our geographical position permits us to ship our surplus production of eggs to arrive in England at the times of greatest scarcity. This is so in normal times, and there is little doubt but that for some years the effects of the present war must make for lessened supplies from Russia and Austria. That we shall soon avail ourselves of this market I have every hope.

#### The Reason for Oversea Shipment.

Every year we have a season of great production, and every year during that period—from August to December—we witness low prices. Although during the last few years—owing to the effect of the 1906-7 shipments to England—prices have been better than

in years previous to 1906. Still, we are in danger of seeing eggs 6d. a dozen in Adelaide during those months. It has become a regular practice for large consumers, speculators, and others to avail themselves of this period of cheap eggs. These cheap eggs are pulped, cold stored, and pickled for use and for sale when in autumn fresh eggs are scarce and dear. Now, it is evident the interests of this class of buyer and those of the poultry breeders do not coincide. The poultry breeder naturally expects that, if his skill enables him to breed fowls which lay in autumn, he should get the increased price and not be subjected to competition in the way of stored eggs, which he, no doubt, sold at a trifle over cost of production. If a fair proportion of the surplus eggs are shipped to England each year, the autumn price will return the poultry breeder his fair share of profit.

### **The Householder.**

Some householders would like to buy eggs at threepence per dozen. One expects such people in any population. They have their remedy. Either they should forego the use of eggs, if they are too mean to pay a fair price for them, or better still, they should keep profitable breeds of poultry and have their own daily supplies at cost. With few exceptions every householder in the State should keep sufficient poultry for his or her needs. Such a course will not influence markets, because the market our big breeders want is an oversea market for the surplus and the town trades of Australia for ordinary supplies. The more poultry there are, and the greater the production, the better chance there is of adjusting prices fairly.

### **Farmers and Other Producers.**

I am naturally optimistic, and yet the dry seasons we are experiencing are what one expected. I have seen other dry seasons and poor crops, and I remember many cases where the poultry saved the situation.

The producers' role in life is to make the best of existing conditions at all times and to gather what worldly possessions he can. In a climate like ours poultry can be profitably included in every rural calling. Even in the worst years there is generally enough wheat of a sort from which the hens will elaborate eggs worth money. If farmers and others whose holdings are in regions of doubtful rainfall would remember Joseph's interpretation of Pharaoh's dream, and act upon that good advice, they would always reserve enough grain for the poultry to turn into eggs. In some of the districts famous in former times for the production of eggs

one recently saw almost as many motor cars as eggs. A big flock of modern commercial hens is also worthy of the motor car owner's attention.

### **The Fox.**

This curse is belauded by some who hope to escape the trouble of eradicating rabbits. The fox does infinitely more harm than good. It is a serious menace to the poultry industry. The fox, like the other introduced pest, the rabbit, seems to be acquiring special local forms of villainy. As the fox is with us, the only sensible thing to do is to erect fox-proof enclosures in which the birds may be kept in safety.

### **Three Essentials.**

There are three main essentials to success in poultry keeping, viz.:—Housing, breeding, and feeding. In the space at command these points can only be outlined. If you are interested and wish to progress, you have only to write and full information will be supplied gratis.

**Housing.**—In the Poultry Section of the Departmental Exhibit at the show there is a model showing the general arrangement suitable for an average farmer's poultry. Briefly, in a large fox-proof enclosure the following accommodation is provided:—(a) Breeding pens. In these you place selected stock birds so that you may breed with a definite object. (b) Chicken rearing pens, where every attention can be paid to the growing stock. (c) Cockerel pens, so that all surplus male birds may be penned up, thus insuring that all the eggs produced, other than in the breeding pens, in the breeding season, are infertile. (d) A laying house for the accommodation of unmated hens, for the production of infertile eggs for market.

Plans and lists of material can be obtained on application.

**Breeding.**—Many farmers keep racehorses, but to win a flat race they never enter their Clydesdales. Nor do they put the flat racers in the wheat waggons. If, therefore, eggs are the object in view, keep White Leghorns of a well-proved, high laying strain. Where eggs and meat are wanted keep a general purpose breed. These will lay a fair number of eggs, and will make up the shortage by giving you fine table chickens. On this important question of breeds suitable for your locality you can get advice if you ask for it.

**Feeding.**—Wheat is the staple in the North, but in the South-East one can use the fine oats grown there to advantage. Give as much variety as possible, and do not overfeed. I am glad to see so many farmers growing summer green feed. Green feed is of the greatest value in feeding poultry.

### Other Points.

Poultry ticks are far too common, and this state of affairs is a grave reflection upon many. It is of no use beating about the bush in this matter—it is important, and every owner of tick-infested premises should take early action. You can get correct information as to the proper methods to adopt. All vermin should be eradicated. Red mites, biting and sucking lice, &c., destroy thousands of birds annually. They can be eradicated easily.

Gather the eggs once a day in cold weather, twice a day in warm weather. Send into market two or three times a week. Yard up all male birds and market none but infertile eggs. Pack the eggs properly, and see that the shells are clean. You producers collectively are losing £60,000 a year through lack of attention to these matters.

Market your table birds while they are young; feed them well, so that the buyer has well-fattened, choice specimens—not half-starved scraggs. Remember the buyers—they fix the price largely. Remember also the consumer—the one you should cater for. Supply the consumer with plump, young, tender table poultry, and he will buy, and buy again and you will prosper, because there is good money in this business. Forward all live birds in proper crates. Allow 17in. head room for fowls and ducks. Do not overcrowd the crates, which must have close bottoms. Turkeys require much more head-room, so also geese. Provide in each crate one or more water vessels. Avoid sending poultry on a journey during a heat wave.

Make a small egg cellar where you can store the eggs and keep them cool. Such a cellar will not cost much money, and should be on every farm. Why not use proper egg crates, and forward your eggs direct? At any rate, use sound cases and sweet chaff. Do not use dirty boxes smelling of kerosine, nor dirty, musty chaff. Eggs taint very freely. The consumer does not approve of eggs tasting of musty straw, kerosine, onions, or raw potatoes.

### Some Facts.

The infertile egg is far superior to the ordinary fertilised egg. Infertile eggs are those produced by unmated hens.

If you keep an egg it loses weight through evaporation. Fertile eggs soon become unfit for human consumption.

When you mate up the breeding hens, a percentage of the eggs will prove fertile three days afterwards, and after the seventh day may be relied upon, if the male bird is all right.

On the average all eggs laid after the seventh day after removal of the male bird are infertile. Occasional fertile eggs, however, are laid 20 to 30 days, or at longer intervals after removal of the male bird.

Eggs are not fertilised in the ovary, but in the upper portion of the oviduct or egg tube. In mated hens this tube is generally swarming with countless spermatozoa—these remain alive and active for various periods, contingent upon the condition of certain fluids secreted in the oviduct. In the case of the turkey the spermatozoa retain their activity for a long period, hence the fact that one good service suffices to fertilize all the eggs in a batch.

You cannot foretell the sex of the chicken resulting from any egg.

By breaking an egg into a cup an expert can generally determine if it was fertile or not.

By careful scientific breeding you can greatly improve your poultry.

Pure breeds are superior to crossbreds. The immediate result of a cross is generally loss of egg production.

Laying is a matter of strain. It is a character which has been or may be fixed in a family of birds by careful breeding carried out during several years. You must continue to breed carefully.

### **General Reminders.**

Pioneer farmers should include a flock of poultry in their equipment. The hens will buy the groceries for you in addition to supplying eggs and later on table poultry.

Those who are too prosperous to bother about the few hundreds which can be made annually from poultry should maintain a good flock as an example to the less prosperous.

Cultivate in your children an interest in poultry. It keeps them occupied and amused; it provides pocket money, teaches observation, and keeps them at home and away from undesirable quarters.

Provide decent houses and safe yards for the birds. Feed them properly, and see that they have fresh, clean water at all times; also grit, gravel, and green food.

Members of country branches of the Bureau should give more prominence to this valuable industry. It is far more than a side line.

Think the matter out. Write for information. You can rely upon a prompt answer. Advice given freely about housing, breeding, &c., suited to your particular requirements. Get ready for a good start upon a new basis next autumn. Time is precious—lose none—there is no time like the present. Write or call.

## PARAFIELD EGG-LAYING COMPETITION.

### REPORT FOR AUGUST.

The weather has been abnormally dry, and, while favorable as regards egg production, has been disastrous in other directions. The rainfall was very light, and the total fall amounted to 37 points only.

Laying has been satisfactory during the period under review, and averages have been well maintained. In comparing results with those of former years it is necessary to remember that there are 10 birds in each pen this year as against six in former competitions.

The health of the birds has been good, they are looking bright and healthy, although, as may be expected, there have been losses. Many of the deaths occur suddenly and no outward signs indicate any common cause. Leg weakness, due to faults in breeding, has been somewhat common. In Section 1, a hen in pen 41 died after a protracted attack of leg weakness, evidently due to kidney trouble; and in pen 39 a hen was found dead, the exact cause was not ascertained. In Section 3, also, a hen was found dead, no outward cause apparent. One bird in pen 35 contracted chicken-pox; this is an abnormal case, due to the nature of the season.

*Broodiness.*—In Section 1 there were no cases among the competitors. Several pens, the eggs from which failed to reach the required standard in weight, are being retained for observation, and from these pens three cases of broodiness were recorded. In Section 3—single-testing, White Leghorns—there were no cases of broodiness, but in Section 4, general purpose breeds, there were two Buff, four Black, and three White Orpingtons, two White Rocks, and one Silver Wyandotte, all of which were broody.

*Greenfood.*—The effects of the drought has been to dry up a good deal of the natural greenfeed. This includes Cape weed (so-called dandelion), native geranium, clovers, sow thistles (miscalled milk thistle), and other herbage very valuable as greenfood. There is, however, great abundance of lucerne, kail, and rape. A bore will provide water sufficient to irrigate a large area of fodder crops.

*Visitors.*—During the month 40 visitors inspected the poultry station. Lady Galway, accompanied by Miss Macaulay, honoured Parafield with her presence and was much interested in the stock, housing, and general operations. Professor William Bateson and Mrs. Bateson also spent a morning inspecting the plant. Both visitors were keenly interested in the single-testing section and in all the breeding experiments which are following on the work inaugurated at the former poultry stations. The mammoth incubator, capacity 5,000 eggs, is now installed and will be of interest to visitors. Special visits are now being arranged.

D. F. LAURIE, Poultry Expert.

## THE WHEAT MARKET.

As a consequence of the war, and probably more particularly the drought, business on the local wheat market during August was very restricted. Prices advanced in keeping with the rise on the London market, but the increase in rates was not so great as many anticipated. Writing under date London, July 31st, which, of course, was before England and France were forced into the fray, Beerbohm states:—"If the war be confined to Austria and Servia, it will have little effect on the wheat trade as far as supplies are concerned, but if the big European countries be drawn into the conflict, the position will be altered as, with shipments from Russia cut off America would have practically complete command of the situation. However, with the new crops only now being harvested, the quantities of native wheat available are larger than they would be at any other time of the year, and, therefore, there can be no scarcity, say in Germany, France, and Italy, for many months. With regard to the United Kingdom, our crop forms such a small proportion of our total requirements, that the situation is entirely different, large and regular imports being necessary. Fortunately for Europe, but unfortunately for America large quantities of wheat have been sold at peace level prices.

"As will be seen by the following tabular statement, present indications are for a world's wheat crop about 30,500,000 quarters smaller than last year.

STEAMER FREIGHTS.—(September 1st).—The European war and the drought in South Australia have caused a cessation in chartering. The rates given below are consequently nominal. Full cargoes, Port Adelaide to United Kingdom, 25s. per ton (8d. per bushel); to South Africa, 27s. 6d. per ton (8½d. per bushel). Parcels, Port Adelaide to London, 20s. per ton (9½d. per bushel), plus 25 per cent. war surtax; to South Africa, 26s. per ton (8½d. per bushel), plus 25 per cent. war surtax; Port Adelaide to Melbourne, 12s. per ton (3½d. per bushel); to Sydney, 14s. 6d. per ton (4½d. per bushel).

SAILOR FREIGHTS.—From South Australia to United Kingdom, 25s. per ton (8d. per bushel); to South Africa, 22½d. per ton (7½d. per bushel).

## DAIRY AND FARM PRODUCE MARKETS.

---

A. W. Sandford & Co., Limited, report on September 1st—

**BUTTER.**—Though increasing quantities of both cream and butter were received throughout the month, supplies have not been equal to trade requirements, so that we are still depending on the east for the shortage. Values locally are ruled by inter-State quotations, and any alteration in the neighboring States is immediately reflected here, with the result that rates came back 2½d. during the month. "Alfa" is selling at 1s. 2d. per pound; "Primus," 1s. 1d.; choice separators and dairies, 11d. to 1s.; store and collectors', 8½d. to 9½d.

**EGGS** had a rapid fall in prices in the early part of the month until pickling rates were reached, which steadied the market, and values later on advanced. Hen eggs are now 9d., and duck 10d. per dozen.

**CHEESE** is experiencing a seasonal easing, but the turnover has been very extensive. No doubt the high prices ruling for fresh meat is causing a better consumption in this line. Present quotations, from 6½d. to 7d. per pound for large to loaf.

**BACON.**—Local supplies have increased, and sales have been on the slow side, with the result that rates have eased somewhat. Best factory cured sides are selling at 9d. to 10d.; cooked hams, 1s.; uncooked, 10d. to 11d. per pound; lard in skins, 8d.; bulk, 7d.

**HONEY** continues to find a brisk inquiry. Prime clear extracted is being placed at 3d. to 3½d. per pound; beeswax, 1s. 2½d.

**ALMONDS**, also, are in good request, brandis selling at 7½d.; mixed softshells, 7d.; hardshells, 4d.; kernels, 1s. 6d. per pound.

**LIVE POULTRY.**—The catalogues during August were very extensive. As demand throughout was brisk, nice rates were secured. With the high figures ruling for fresh meat satisfactory prices are likely to prevail for some time to come, so that consignors would be wise to send on all possible. Good table roosters brought 3s. to 3s. 7d. each; nice-conditioned cockerels, 2s. to 2s. 8d. each; hens, 1s. 8d. to 2s. 3d. (light sorts selling lower); ducks, 2s. 4d. to 3s. 3d.; geese, 5s. to 5s. 6d.; pigeons, 6d.; turkeys, from 7d. to 9d. per pound live weight for fair to good table birds.

**POTATOES AND ONIONS.**—There has been a strong demand for potatoes, and as Mount Gambier growers were disinclined to sell, the bulk of our requirements have had to be imported from Victoria. Onions—Local supplies being nearly exhausted this market is now dependent on Victoria, and prices have substantially firmed. Present quotations—Potatoes, £5 10s. to £6 10s. per ton of 2,240lbs. on truck Mile End or Port Adelaide; 6s. 6d. to 7s. 6d. per cwt. in the market. Onions—£10 per ton of 2,240lbs. on truck Mile End or Port Adelaide; 11s. per cwt. in the market.

## RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of August, 1914, also the average precipitation to the end of August, and the average annual rainfall.

| Station.                   | For Aug., 1914. | To end Aug., 1914. | A'v'ge. to end Aug. | A'v'ge. Annual Rainfall | Station.               | For Aug., 1914. | To end Aug., 1914. | A'v'ge. to end Aug. | A'v'ge. Annual Rainfall |

## THE AGRICULTURAL BUREAU.

### CONFERENCE OF EYRE'S PENINSULA BRANCHES.

The third Annual Conference of the Eyre's Peninsula Branches of the Agricultural Bureau was held at Cleve on Tuesday, August 4th. The Advisory Board and the Department of Agriculture were represented by Mr. John Miller, P. H. Suter (Government Dairy Expert), and G. G. Nicholls (Secretary Advisory Board). Delegates who signed the roll were:—Elbow Hill—A. O. Dawkins, H. W. Wheeler; Yadnarie—L. H. Marston, O. Dreckow, H. S. Bauer, F. Stubing, F. W. Dreckow, G. A. Dreckow, J. H. Kruger, C. E. Stubing, G. B. Kobelt, A. Jericho, J. A. Kruger, S. H. Pearce, J. J. Deer, W. J. Johnson; Yabmana—J. F. Robertson, C. W. Story, A. Robertson, J. H. Frost, F. A. Beinke, A. R. Beinke; Miltalie—J. S. Story, W. E. Hier; Roberts and Verran—H. J. Crutchett, J. C. McCallum, R. G. Plew; Mangalo—J. H. Cleave. There was also a number of visitors present, making an attendance of about forty.

Mr. H. Masters, who presided, in extending a welcome to the visitors from the mainland and to the delegates and others, said that farmers in this district to-day had two great advantages that were not enjoyed by the earlier settlers. One was the more modern application of scientific research to the problems of the producer, and the other was the knowledge gained through experience by pioneers and made available to those who had settled on the land in later years. In this connection the publication of the reports of Bureau meetings had done a great deal to improve the standard of farming. The experience of the individual had been made known to the multitude.

#### OPENING ADDRESS.

Mr. John Miller, member of the Advisory Board of Agriculture, opened the Conference at the request of the Chairman, and in an interesting and chatty address traced the development of agricultural practice and methods from the "fifties" to the present day. At the beginning of that period single-furrowed ploughs were used on wheat lands, the crop was cut with a sickle and threshed with a flail. It was hard work to get enough grain to sell. Land was sold by the Crown at auction and land jobbers formed a ring and made it difficult for farmers to secure land without their agency. After a while land became "wheat sick," and the problems of the farmer were great

indeed. The advent of John Ridley's "stripper" marked the commencement of a new era. The "Strangways Act" enabled men to secure land at fair values, and the establishment of the Agricultural College at Roseworthy led to the advocacy of fallowing land for wheat and of the application of superphosphates to the soil. Year by year improvements were effected in machinery and implements until the present high standard of efficiency and labor-saving devices was reached. Speaking of the future development of the agricultural industries, Mr. Miller said that regard should be given to the indigenous vegetation in new country, as this was an indication of the best way to deal with the land. For example, saltbush and cottonbush where found was a standby in dry seasons to carry the stock on after the grasses had all disappeared. It would be a great blessing to many farmers if a grass could be introduced that had fair powers of drought resistance, and he thought the Agricultural Bureau might well experiment with grasses along these lines. To start such an enterprise here he had brought parcels of seeds of Japanese millet and Rhodes grass, and would distribute these among some of the Branches represented at the Conference. He wished the Conference every success, and with pleasure declared it to be open.

#### APOLOGIES FOR NON-ATTENDANCE.

At this stage the Secretary delivered a message from Professor Perkins, Director of Agriculture, who had been unable to attend, to the effect that the Professor would make a tour of the agricultural areas of the Peninsula after the September show, and hoped at that time to meet many of the members of the Bureau. The Chairman of the Advisory Board (Mr. George Laffer, M.P.) had been unable to attend owing to Parliamentary duties.

#### MIXED FARMING.

A paper on mixed farming for this district was contributed by Mr. F. A. Beinke (Yabmana Branch). In a district such as this, said the speaker, it was always wise to have other sources of revenue than the main industry of wheat-growing. Where there was sufficient labor, eight or ten milking Shorthorn cows should be kept. This breed could be profitably turned into beef when milking days were done. He considered butter should bring in £10 per annum per cow, and in addition the progeny would bring in revenue. Sheep paid well, provided that the farmer did not overstock. His near neighbor had realised 18s. per head from well-fed lambs, and the ewes should bring in a further 6s. or 7s. each for wool. Pigs paid well, especially in conjunction with cow-keeping. With the demand for export meat the present high prices were likely to continue. Unfortunately few owners of fowls paid sufficient attention to ensure profitable returns. If properly managed, poultry paid well but they must be properly fed. If this were done there would be no complaints.

that they worried the horses when feeding. A garden properly managed was a source of profit as well as of pleasure, and beauty to the homestead. Farmers in this district should not have to buy vegetables.

#### DISCUSSION.

Mr. J. N. McCallum (Yabmana) considered dairying would not pay in this district owing to the distance from the market. Most of the butter used here was imported from Victoria, and not until the local farmer could compete with the Victorian prices would the industry pay here.

Mr. A. O. Dawkins (Elbow Hill) agreed that fowls seldom received fair treatment. If hatched in the first week in September they would lay when eggs were at their highest price. With respect to sheep he could say that during the past three or four years he had made more money from the "woolly backs" than one was ever likely to make from wheat-growing under such dry conditions as had prevailed.

Mr. P. H. Suter (Dairy Expert) said that although he could not advocate the keeping of a "dual purpose cow" in general dairying, he realised that for farmers who only wanted three or four beasts some such breeds might be best. He recommended the Shorthorn-Ayrshire cross, or better still, the Jersey-Shorthorn cross.

Mr. B. B. Crosby considered that every farm should have a cow or two. It would pay to stable-feed a good cow, if such course became necessary.

The Chairman said that in his view mixed farming was the only practical policy for farming on Eyre's Peninsula. Too many farmers had all their eggs in one basket. It always paid to keep the best of any form of livestock. It was a disgrace to the district to be importing butter. As a storekeeper he knew that many farmers bought butter, whereas they ought at least to keep enough cows to supply their own needs. That done, lambs paid perhaps better than any other form of stock at present.

#### CONSERVATION OF FODDER FOR USE ON THE FARM.

The following paper, written by Mr. H. F. J. Hill, of Salt Creek Branch, was read by Mr. H. P. McCallum (Secretary to Conference):—"The question of conserving fodder has been overlooked by most farmers in this district. In previous years, when seasons were good, crops of a fair length and weight could have been cut and dealt with by heading or threshing and carefully stacking the straw. I strongly recommend the use of the header, having had a good deal of experience with this machine. The inexperienced man usually says that the cost of handling a crop in this manner is too great. I therefore offer the following suggestions: When you have decided what portion of the crop to harvest and put through the header, cut it with the binder, being careful to tie the sheaves as near the butts as possible. These when headed will not fall to pieces. The crop must be cut about 10 days before it would

be fit to reap. The sheaves can be stooked close soon after they are cut, and remain there until you are ready to do the heading. To save a lot of work and expense do not stack the sheaves until they have been headed. When you are ready to deal with the grain it can be carted straight to the machine, keeping two wagons regularly carting; one will be loading and the other at the machine. Working the two wagons alternately throughout the job, three men can manage with ease. The stacking of straw and other work at the machine can be done by four other men. Thus the whole concern can be managed with seven men, putting through an average weight of about 16 tons per day. I do not advocate heading straw for sale purposes, but solely for a stand-by in lean or droughty years, although a ready sale is found for headed straw this year at an enhanced price. It is not advisable to head a crop unless the yield be 12bush. or over. Fodder may be conserved in other ways, and he who so provides in good years and does not overstock will not have to depend on his neighbor for his surplus cocky chaff to keep his stock alive. Headed straw, if properly stacked, will be as good in 10 years as on the day when it was stacked. When chaffed and concentrates are added it makes a good substitute for hay chaff, and horses will do well on it."

#### DISCUSSION.

In the discussion Mr. H. H. Wheeler (Elbow Hill) thought the system of heading was not generally practicable, owing to the difficulty of getting labor. Oat straw was very valuable and should never be wasted. Cocky chaff was valuable and should be saved. Many farmers had made a great mistake in replacing strippers with complete harvesters.

Mr. W. Hier (Miltalie) agreed with the writer that it was not worth while to "head" a crop yielding less than 12bush. to the acre. In his opinion chaffed straw was not as good as cocky chaff. In either case molasses and bran must be added to the more bulky food.

Mr. A. O. Dawkins advocated the cutting of straw immediately after stripping—stacking in layers with salt and dry molasses sprinkled between. This made a good stack of feed in the paddock. The horses would eat every straw. For protecting and feeding cocky chaff with a minimum of labor some farmers had erected a roof shed under which the stuff was heaped. This was fenced round at a short distance, and the cocky chaff was then scraped out to within reach of the stock whenever desired.

Mr. J. F. Robertson (Yabmana) thought farmers should pay more attention to the conservation of recognised good fodders, such as cereal hay.

The Chairman and Mr. Suter advocated the making of silage. The Chairman had made silage in the Bute district, and had had occasion to feed it to horses as well as cattle. The horses did remarkably well on it with the addition of a little hay chaff. Stock needed some such succulent tonic as this in the dry seasons.

## THE CARE OF THE FARMER'S COW.

The afternoon session was inaugurated by an address from the Dairy Expert. Although the possibilities might be greater later on for dairying, said Mr. Suter, for the present he would deal with the care of the cows, where farmers had one or two for their own use. The cow should not be kept in very high condition just before parturition, or danger of milk fever would be present. Immediately before calving one or two bran mashes or some green feed could be given, but not enough to make a big bag of milk. She should be kept in a quiet place and left to herself. On no account should she be interfered with unless there was a malpresentation of the calf. After delivery the mother could again have bran mashes, leaving the calf with her for, say, 24 hours. A few drinks of the "beastings" would give the calf a good start in life, but if left with the mother for two or three days the maternal instinct would be so much developed as to cause the cow to be considerably troubled upon separation from her offspring. Regular feeding with good nutritious rations must be observed right through if a cow was to be kept to profit. There was no doubt of the truth of the saying, "All the milk goes down the mouth." It was a great mistake to have a cow served the first time she came on season, say, at three weeks after calving. At least 10 weeks to three months should be allowed to elapse. A certain quantity of blood was required to feed the foetus, and therefore the period of lactation was reduced too much if the cow became pregnant so soon after calving.

## FEEDING.

If cocky chaff was used at all there must be the addition of concentrates in the proper quantities for milk production. Food was used for the generation of energy, to replace waste in the system, and for the production of milk or to add condition to the beast. Molasses was not alone sufficient to add to cocky chaff, but bran or lucerne must be fed as well. Lucerne was a splendid fodder. It could be fed green in summer and as hay in winter. There was a vast area in South Australia which, if given a fair trial, would grow payable crops of lucerne without irrigation. Of course a greater number of cuts would be secured with irrigation, but two good cuts could be grown in such areas on the natural rainfall. The best time to cut was when about one-eighth of the crop was in flower. It was then most nutritious. Cereal hay was well known as a splendid fodder for cows, but unfortunately they seldom got it on most farms. Twenty pounds to 25lbs. per day, with 6lbs. of bran, or sometimes a little pollard, made a good ration. For every gallon of milk produced a cow needed 5galls. of water, so that an adequate supply was of great importance. If compelled to drink stagnant water cows would take less than they really required and the milk would fall off in quantity. The health of the cow would also be affected. It always paid to treat a cow kindly. Dogs were seldom needed, but a well-trained dog was preferable to a bad-

tempered man to deal with milch cows. Rough treatment invariably caused the cow to hold her milk, and, owing to the control she had over the secreting organs in the udder, this was quite an easy matter for her to do.

#### FEEDING CALVES.

It was a good practice to knock bull calves on the head and give as much milk as could be spared to the heifer calves. The beastings contained about 17lbs. of albumen to 10galls. of milk, as compared with about  $\frac{3}{4}$ lb. in average normal milk a few days later. This was provided specially for the calf. The latter should be fed on whole milk three times a day for the first 10 days, after that a little skim milk could be added, gradually increasing the quantity until at, say, six weeks skim milk fortified as follows formed the meal. It was important to feed at the right temperature of 96° to 98°. Cold milk led to digestive trouble, scouring, and often death. Pure crushed linseed added to skim milk, molasses, and pollard kept the calf going until it was able to take chaff and a nice picking of grass. Treated in this way the lacteal organs would develop, and by six months the heifer should be ready to wean and gradually work on to the paddock. She must never be allowed to get a check from insufficient or improper feeding. In reply to questions, Mr. Suter said that a Jersey heifer should not be mated until 15 or 16 months old at the earliest and if well developed. If she had received any set back she should be 18 or 20 months old. Shorthorns and Ayrshires could be mated at 20 to 24 months—to be in milk at about two years and nine months. It was a good plan to handle heifers before they were very forward in calf, so that they would become accustomed to the bail. The bag would be somewhat hard, and if rubbed with olive oil before calving the skin would expand more easily and chafing would be avoided. Regular milking was important. The difference in yield where regular practice was observed was quite surprising. It had been known to reach as much as half a gallon difference per day. Heifers should be milked right on after calving, and not allowed to “cut out” at three or four months; otherwise a habit would be formed, and they would go off after every calf at about that time.

#### PRACTICAL WORK IN THE BUREAU.

The Secretary to the Advisory Board of Agriculture delivered an address on some phases of Bureau work, laying stress on the need for practical work as well as the reading of papers. The latter no doubt had great value, but actions spoke louder than words, and the Branch that showed how to do a thing, as well as advocated it, had a much greater effect on the standard of agriculture in its district than one whose efforts began and ended with talking. Ample evidence had been given that day that there was plenty of scope for experimental or demonstration work. Trial plots of grasses and fodders, as well as tests with quantities of manures and varieties of wheat, could with

great advantage be undertaken by the Branches of the Bureau. In the discussion which followed it was agreed that much experimental work must be done in these new lands, and that the Bureau could materially help in that work.

### EVENING SESSION.

#### THE VALUE OF THE BUREAU TO THE PRODUCER.

Mr. W. E. Hier (Miltalie) read a paper to the following effect :—" Let us first take a view of the growth of this organisation since its foundation 26 years ago. At first it was the practice to have only a limited number of members in each Branch, and they, as a rule, were nearly all farmers. As time went on the system was modified, until eventually all those who had an interest in the advancement of agriculture were encouraged to join and take an active part in the working of a Branch by reading papers and by conducting experiments. The Bureau helps the producer, because it encourages farmers to experiment, and this is the principal means of discovering the best sorts of wheat or other crop to sow and the right time to sow it; also the best manures to use, the best way to work the soil, and the right time to perform the various operations of tillage. The forming of a Branch of the Agricultural Bureau in any district should raise the standard of farming in that district. Experience and knowledge are needed for any man to make a success of farming. The seasons may go against the man, but he can learn from experience the best way to cope with adverse times. By reading the reports of the Bureau meetings in the *Journal of Agriculture* (which is a very valuable paper for the producer) we learn by the experience of others. We must not overlook the fact that all the members are to some extent responsible for the good that can be done by the Bureau. Everyone can do his share in bringing under notice some important matter, so that all producers are enabled to receive some hints to their advantage. Those who take up new blocks can learn from the experience of others how to lay out their new farm buildings, so that in years to come much needless expense will be saved. Very often as much information is gathered from the discussion following a paper as is imparted by the paper itself. Every Branch should, therefore, encourage free discussion and give everyone an opportunity to express his opinion. This will help the younger members to gain confidence, and will give them more interest in the meetings. Some may think that all the subjects have been dealt with, and that the time is past for papers to be written on implements, harness, fences, &c., but I cannot quite agree with them. We are not all old farmers or scientific men, and many old farmers make mistakes in the care of their implements, horses, and harness,

so that I believe a paper on any of these subjects may be useful. In conclusion I would say that in my opinion the founder of the Agricultural Bureau is worthy of our greatest honor for being the means of putting a lot of useful information in the way of the producer, and thereby helping him to help himself." Commenting on the paper, Mr. E. Story, of Miltalie, said that one great value of the Bureau system was that through it farmers were brought more directly into contact with the Government departments, such as those of stock and agriculture. It also undoubtedly helped the young men to develop as speakers, and made them more observant. The Chairman said that, properly managed, the Bureau was calculated to lift the producers of any district to a higher plane of agricultural practice and success.

### IMPROVED METHODS IN FARMING.

A paper under this title was contributed by Mr. H. Wheeler, of Elbow Hill, as follows :—" Past experience cannot always be relied on as a guide for the future. As the seasons change so must the farmer change his ways of working. In the first place I think there is still much room for improvement in our system of cultivation. The idea seems to have been prevalent in the past that intense culture is suited only to heavy soil in wet districts, but experiments with various systems of dry farming have proved that dry country requires even more working than does wet. Heavier cultivation will keep the land clean, conserve the moisture, and thereby enrich the soil. My opinion is that the more work we put into the land the more profit we shall get out of it, and the time is not far distant when it will be recognised that in a district with the rainfall we have here it will pay to grow wheat on fallow ground only. A farmer with from 800 to 1,000 acres of land should have a better chance of making good by sowing about 300 acres a year, and always fallowing that amount, than the man with 2,000 acres who scratches in 800 or 900 acres and chances his luck on stubble or grass land. The farm should be so subdivided as to enable one-third or thereabouts to be cropped at a time, and fenced to keep back all stock. By doing this each paddock would carry a crop of wheat every third year. By adopting this method we should get the seed in at the proper time, and should find it much easier on the horses, as all the heavy ploughing would be done in the winter when the ground is in better condition for ploughing and time is more plentiful. It often happens at seeding time that we have to neglect the fallow to plough up some grass or stubble land while it is wet. By having all the wheat land fallowed this trouble would be removed and we could go straight ahead at the right time. I prefer the fallowing done as early as possible, and where autumn fallowing is possible it would certainly be the most profitable, as it would get the full benefit of the winter rains. By repeated harrowing or cultivating during the winter and spring the moisture is conserved and weeds are destroyed. After cropping it may not always be practicable to leave

out all the stubble land, and in such case oats could be sown on a portion of it and still leave out enough for winter feed for the stock. The return from 80 or 100 acres of oats should make up all that is needed for hay, etc. Another important item is the selection of seed wheat. In order to obtain the best variety to suit the locality every farmer should set apart and specially prepare a piece of ground for the growing of seed wheat, and the greatest care should be exercised to keep the varieties clean and unmixed. Mr. Coleman, of Saddleworth, speaking on wheat improvement recently, said—'We may improve our wheat in three ways, viz., by grading, selection, and cross-breeding.' By grading and sorting the cleaned wheat into three or four lots, the first grade would be the best plump grain, the lowest grade consisting of the small, cracked, and pinched grains of wheat and foreign seeds. Professor Lowrie said last year that 8 per cent. to 15 per cent. of these smaller grains could be removed, and that Dr. Colt, of New South Wales, had shown by scientific tests that there was an advantage of 18 per cent. in favor of sowing only the larger grains. Allowing only 10 per cent. this would mean an addition of 2,000,000 bush. to our annual wheat crop. The saving of the cracked and pinched grain alone for fowl and pig feed would in many cases justify the trouble of grading the seed. As to the best variety of wheat for this district I think Gluyas is still best, though for the lighter land near the coast J4 is a good wheat and stands up much better than Gluyas. German Wonder is a good yielder and a splendid hay wheat; rather late for the plains, but is admirably suited to the heavier land in the hills. Another important point which I wish to touch upon is fat stock for the local market. It seems unreasonable that in a district like this, year after year our butchers have to import meat from other parts of the State. Here we have a very large district, most of it good grazing country, with a comparatively small population, and yet we cannot grow enough meat for our own demands. In the past the chief reason has been scarcity of water. With the advent of the water schemes we have going on we should be well supplied in this direction. I firmly believe that by careful stocking and totally exterminating the rabbit pest we could more than double the number of sheep and cattle at present kept in this district. If every farmer were a little more careful in the spring time, when the grass is growing, to remove all stock from the paddock and keep down all the vermin on it until the end of the summer, when all the stubble feed is done the stock could be kept in a more even condition. A hundred acres reserved in this way should top up 200 sheep in the average grass land in this district. They would then be ready for market at a time when meat is scarce and prices are highest."

Mr. J. P. Story (Miltalie) opened the discussion by saying that on such a farm as that instanced in the paper he would sow with oats the whole of the 300 acres of stubble to be left out for grazing.

Mr. S. H. Pearce (Yadnarie) said that Gluyas wheat did well on stubble, but he preferred later varieties on well-fallowed land. Oats would not stand dry weather as well as would wheat; but he thought it advisable always to sow a small area to this cereal, moving from place to place to check takeall.

The Chairman considered it better to sow oats in the stubble than merely to leave the stubbles for such adventitious feed as might grow. It paid better to graze oats on stubble than to leave the crop for hay.

### HORSE COLLARS.

The members of the Yadnarie Branch introduced the subject of restuffing horse collars with old hair, a practice said to be common among saddlers. Several speakers said the matter was of great importance in that there was no "spring" in the old hair, and some considered disease germs were carried from one horse to another by this means. Respecting sore shoulders, Mr. Story contended that far more damage was done through neglect to clean collars than from the use of old hair in stuffing. Finally, a resolution was carried that—"In the opinion of the Conference collars should be stuffed with new hair only."

### EXPERIMENTAL FARM WANTED.

Considerable discussion occurred on a motion recommending the establishment of a Government experimental farm in this district. Most of the speakers were strongly in favor of the proposal, and eloquently set forth the claims of the district for this consideration. Others thought that some of the newer districts, *e.g.*, hundred of Mitchell, had stronger claims than those who were fairly established and able to experiment for themselves. After full consideration a resolution was carried asking the Government, through the Advisory Board, to establish an experimental farm in this district.

Votes of thanks to the speakers, the Chairman, and Conference Secretary terminated the proceedings.

---

### CONFERENCE OF PINNAROO DISTRICT BRANCHES.

---

The Annual Conference of the Branches of the Agricultural Bureau in the mallee districts east of the River Murray was held at the Institute, Lameroo, on Friday, August 14th, and Saturday, August 15th.

The Director of Agriculture (Professor Arthur J. Perkins), the Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.), the Superintendent

of Experiments (Mr. W. J. Spafford), the Conservator of Forests (Mr. W. Gill, F.L.S., F.R.H.S.), the Chairman of the Advisory Board of Agriculture (Mr. G. R. Laffer, M.P.), the Vice-Chairman (Mr. F. Coleman), the Secretary (Mr. G. G. Nicholls) were present, together with the following delegates, representing the Branches below mentioned :—Clanfield—D. A. Orwell, W. Booth, H. R. Hayward, A. H. Wilkins; Geranium—R. C. Jacob, W. R. Goldsworthy, F. Norton, W. Mitchell; Parrakie—M. J. Cooney, A. J. Beelitz, H. Diener; Coomandook—M. Wilkin, E. A. Luxmore; Lameroo—S. R. Sinclair, E. T. Wray, E. J. Trowbridge; Cressy—C. Shelton, W. P. McCabe, J. L. Johnston; Parilla—P. J. Browne, H. G. Johnston; Claypan Bore—J. Gray, D. P. McCormack, M. Robinson, A. Hill; Pinnaroo—C. A. E. Schiller, R. Edwards, F. G. Bonnin, P. H. Jones; Wynarka—E. G. Colton; Wilkawatt—W. J. Tylor, D. F. Bowman, M. A. Neville; Parilla Well—F. A. Webster, J. S. Ferguson, J. W. Johnston, J. E. Johnston. A large number of visitors also were present.

The chair was occupied by the President of the Lameroo Branch (Mr. A. J. A. Koch).

### WELCOME TO VISITORS.

The Chairman extended a hearty welcome to the officers of the Department, representatives of the Advisory Board, and visiting delegates. He paid a high tribute to the work of Mr. Laffer and Mr. Coleman in the interest of producers in this State. He congratulated Professor Perkins on his appointment to the position of Director of Agriculture. His promotion was well deserved, and the work he had accomplished at the Roseworthy Agricultural College had only to be seen to be appreciated.

The farmers represented by the gathering were all engaged in the cultivation of "mallee country," and the result of the deliberations should be of great value. Views expressed would no doubt be criticised, but criticism afforded one of the best means of education.

### OPENING ADDRESS.

Mr. Laffer, in declaring the Conference open, deeply regretted the absence of the Minister of Agriculture (Hon. T. Pascoe), who had fully intended to be present, but, at the last moment practically, had been called away to Melbourne. The Minister was keenly interested in the work and development of the Bureau, and had made it a practice, so far as possible, to attend the district conferences, so that he might note what was being done and get into personal touch with the leading farmers in the various localities. He (the speaker) was extremely glad to see so many delegates, but the large attendance was not surprising because the Branches east of the Murray were generally recognised as being among the most enterprising, enthusiastic, and alert in the State. Professor Perkins's appointment as Director of Agriculture had been a source of gratification. There was no doubt he

merited the choice made by the Government, for at the College he had done work which must contribute materially to the progress and prosperity of the country. The Minister of Agriculture was to be commended for not only the elevation of Professor Perkins, but also for all of the alterations which he had made in connection with the reorganization of the department. A large number of farmers were beginning to realise that the day was coming when they must strike out in new directions, and of course they were looking to the officers of the department, to a large extent, for guidance and instruction. The results recorded by the several experimental stations were going to prove of considerable help to the primary producers, and it was encouraging, therefore, to learn that Professor Perkins hoped shortly to make those institutions much more efficient and effective than they were now. In conclusion, he regretted that owing to illness in his family the Poultry Expert (Mr. D. F. Laurie) had found it impossible to attend the Conference, which promised to be of appreciable advantage to all of them.

#### WINDBREAKS IN THE MALLEE.

The Conservator of Forests (Mr. Walter Gill, F.L.S., F.R.H.S.) addressed the gathering on this subject. He indicated that the principal factors in creating the necessity for breakwinds were indiscriminate clearing of the land, the invasion of the country by the rabbit pest, and the trampling of the soil by stock of all kinds, and the destruction by them of much, if not all, of the indigenous vegetation by excessive grazing.

It was quite the most discouraging fact in connection with clearing operations that the wise words of counsel, often given, regarding the need for leaving scrub enough for breakwinds and soil protection had been as often, for the most part, deliberately ignored. The excuse for that exceedingly reprehensible course had always been, "Well, you know, it gives so much extra work. We should have to make breaks between the scrub to be burnt and the standing scrub, and the hindrance is too great to other work." Just so! In the rush to get over as much as possible and put in as large a crop as possible, it certainly did seem a waste of time and energy, looked at in the light of the present; but what of the future, when those who offered such excuses found that their stock required shelter; their crops were blasted by the hot winds that swept over the land unimpeded; and in some districts the soil, too sandy to hold together, was shifted hither and thither. While it was at once admitted that in some places the scrub was too dwarf and low to form a breakwind, in very many cases the mallee was sufficiently large to have given ample protection both to stock and crops had it been left in suitable spots. Not only so, but with careful management on a very simple plan portions might have been cut over periodically in such a way as always to provide sufficient firewood and other material, at the same time maintaining an efficient breakwind. In other places even the small scrub, no higher

than a horse's knees, would have amply protected the lighter soils from the erosive action of the wind, which rapidly blew the sand away whenever the surface vegetation was removed.

The rabbit destroyed the herbage which was to its taste, defiled what it did not eat, rendering everything distasteful to other animals. When in the dry surroundings of the scrub it attacked the perennial bushes and trees, ate their leaves, climbed up the larger ones, and bit by bit barked them until their tops died, and then finished its nefarious work by burrowing down and barking all the roots, thus effectually preventing them from ever sprouting again. Tens of thousands of acres of valuable feeding bushes in some parts of the State had been utterly destroyed by this ubiquitous plague. The only way to check it was to fence off efficiently all lands for breaks or soil protection. Relatively to overstocking, in districts where the rainfall was regular, sufficient, and reliable, the trampling of sandy soil by cattle, great or small, was not of so much importance, but in the drier localities stock so broke up the surface as speedily to ruin its solidity, and cause it to scatter. Lamentable results could be traced to excessive grazing and constant travelling by stock, as well as to the excessive removal of the protecting trees which Nature had provided for keeping the country intact.

With that rapid glance at the causes, they must now look for the remedy, which lay in the formation of breakwinds. These might be considered from two aspects. One, where the soil was firm and could be planted at once; the other where it was liable to be shifted by the wind and must be fixed before any planting could be done. In considering the first point, climatic conditions, in that wide district, distinctly limited the possibility of tree-planting. In the forest reserve at Parilla the following trees had been planted as an experiment:—Sugar gum, blue gum, Murray box, box gum, Yate gum, spotted gum, forest red gum, Maritime pine, Aleppo or Jerusalem pine, Canary Island pine, bulloak, New South Wales swamp oak; and the only trees which were at all reliable were the sugar gum, blue gum, Murray box, the Jerusalem pine, and the New South Wales or Kingston oak, as it was called in Adelaide. To these might be added the tamarisk (*Tamarix gallica*), and then they had the six most promising trees for planting as breakwinds on the firmer lands. All were issued from the nurseries of the Forest Department from time to time. With adequate protection from rabbits, and equally from stock of all kinds, even down to poultry, which would constantly rob the trees of their leaves, if not excluded, fair results could be obtained; but it must be remembered that any neglect in the upkeep of a perfect fence would lead to immediate disaster. The second aspect for consideration was an admittedly difficult one, and the treatment must vary according to the conditions of varying localities. The drier the localities the greater the difficulties, because the time in which remedial measures could be carried out was so much less. The Pinnaroo district was very dry, and the less the rain

the easier the soil shifted where it was too light in character and too exposed in situation. Of the various methods adopted, two seemed to be best suited to the conditions existing in that locality.

One plan was to cover the surface with branches of trees and thus prevent it shifting under the action of the wind. The branches, where possible, should be taken from trees bearing seeds, which, as they fell into the sandy soil, would ultimately germinate and grow up to protect the soil from further erosion. There were several useful trees in the scrub which ought to answer the purpose well. The scrub pine (*Callitris verrucosa*) was one. It could be easily identified by its cones, which were covered with small warts or knobs, and by its bushy habit of growth. Another was the larger pine (*Callitris propinqua*), which usually was a taller and straighter growing tree with large cones showing a few lines running from the top to the base of the sections of the cones. It was not necessary to cut any tree to pieces to get these branches. A limited number could be taken carefully from trees large enough to spare them while leaving each tree in a condition to continue healthy growth. The proper time to do the work was in the autumn, say, about April, when the first rains came, because the advantage was thus gained of having the autumn, winter, and spring months in which the young seedlings could get established before the heat of summer arrived. Another tree suitable for the purpose was the commonest mallee (*Eucalyptus dumosa*) usually found in the stiffer lands, and with moderately sized seed vessels, and the mallee growing on the sandhills (*Eucalyptus incrassata*), which, though smaller in growth, usually had much larger seed vessels. There were other mallees, but those named were the commonest. Should the others be used the effect would be equally good, save in the case of the so-called "gooseberry" mallee (*Eucalyptus calycogona*), easily distinguished by its angular seed vessels. This was not suitable, as it liked the low-lying damper spots. There were two kinds of ti-tree (*Melaleuca acuminata* and *Melaleuca curvifolia*), both of which grew on sandy ridges, and would supply fruiting branches which would seed the ground in the way indicated. The old brush fences had now for the most part disappeared, but it would be no doubt well known to many how constantly young trees, sheaoks, and other trees had sprung up under the shelter they afforded, thus giving a plain illustration of the results which might in due time reasonably be expected from the adoption of the course indicated. With that plan, as with the previous one, the protection of the land operated on by a first-class netting fence was an absolutely indispensable factor.

Another plan which had proved quite satisfactory was to sow or plant the land with several kinds of grasses and plants which would thrive in sandy country, and by their root systems fix the land. The evening primrose (*Oenothera biennis*), well known by its fine pale yellow flower, was one of the plants adapted for the purpose. It was a good fodder plant, but three kinds

of lupins, the yellow lupin (*Lupinus luteus*), the white lupin (*Lupinus albus*), and the blue lupin (*Lupinus hirsutus*), though good sand binders and excellent for green manuring, had seeds which were dangerous to stock, and could therefore not be used on areas to which they would at any time be given even temporary access for light grazing. Among grasses well adapted for the work were the veldt grass of South Africa (*Oryzopsis miliaceum*), and the well known couch and marram grasses. After fixation of the sand by these agencies trees could be planted in suitable spots; but any grazing which might later on be permitted when the vegetation was well established, must be of the lightest description, as heavy grazing would simply mean an immediate repetition of the evil which they had been trying to remedy. Here also an impenetrable fence was an imperative condition if success was to be attained. A measure which had proved serviceable in staying the drift sand over wide areas that favor its adoption was to plough a few furrows close together across the course of the prevailing winds to form a good high crown. The land was then left unploughed, say, half a chain wide. A few more furrows were then made in the same way, and another land was left unploughed until the whole area to be treated had been completed. The drifting sand lodged against the ploughed strips, and further movement was checked. That procedure had been successful on land adjacent to the date palm plantation near Lake Harry some years ago, where the sand drifted a good deal owing to the continued absence of rain. Reliable information from various sources showed that in other parts the same plan, either with or without the sowing of wheat or other cereals over the area, had been effective. Through the courtesy of the Director of Irrigation he learned that a similar practice had proved to be highly successful in Kansas, United States of America.

#### DISCUSSION.

At the conclusion of the address the points raised were vigorously debated by the delegates. In the course of this Mr. Beddome (Parrakie) mentioned that *Paspalum dilutatum* flourished in his district, and this might effect a solution to the problem of drift. Mr. Edwards (Pinnaroo) had planted a number of sugar gums, and these had done particularly well. Mr. Neville (Wilkawatt) said the native sandalwood was one of the hardiest trees they had, and if the seeds of this could be collected and sown probably a very effective break would be secured. Mr. Gill referred to the difficulty of gathering seeds of this tree. In order to secure a definite idea of the general opinion of the Conference Mr. D. McCormack (Claypan Bore) moved—"That in the opinion of this Conference, high trees, with bushy foliage on the tops, are more effective as windbreaks in this class of country than shorter trees." This was seconded by Mr. Bowman (Wilkawatt), and carried. Mr. E. J. Trowbridge (Lameroo) then moved—"That in the opinion of this Conference it is unnecessary to plant trees to prevent sandrift in this district,"

and subsequently, "That it is desirable to plant trees to provide shelter for stock," both of which motions received the assent of the gathering. Mr. Jacobs (Geranium) stated that he had successfully grown the following grasses:—*Paspalum dilitatum*, veldt grass, perennial rye grass, Yorkshire fog, Rhodes grass, and Bokhara clover. Mr. Gray (Claypan Bore) adopted the practice of sowing the tops of sandhills with oats early in the season, and feeding them off with stock.

### EVENING SESSION.

#### PLACE OF NEXT CONFERENCE.

It was decided that the next Conference should be held at Tailern Bend, the local arrangements being in the hands of the Wynarka Branch.

#### WORKING LAND WHEN IN A DRY STATE.

Mr. J. Foale (Parilla) read a paper on "The best method of working land dry." The subject, he said, really narrowed itself down to two questions—was it safe to work the land in a dry state, and how far was the procedure practicable? In his opinion the practicability of dry working depended very much upon the condition of the soil and the method to be adopted. Sandhills and sandy flats could be worked easily at any time, but it was generally necessary to wait for rain to deal with the heavy land. If the latter was run over with a share or a disc plough, or even a tine cultivator, to break the surface, even if only an inch deep, it would then be in a good condition to receive the rain when it fell. Immediately after the rain the land should be ploughed in the ordinary way, and a fine seed bed would result. The drilling should be done while the soil was still moist, and the land then should be cross-harrowed. That procedure would pack the soil around the seed and ensure almost immediate germination. Stubble land which had had a good fire over it would generally be found to work freely. The wheat should be drilled in soon after the ploughing, and then the land should be harrowed to cover all loose grains. Harrowing again immediately after the rain would be beneficial, as it would loosen the surface and conserve the moisture. After a keen discussion, it was resolved, on the motion of Mr. Trowbridge—"That, when preparing land for seeding, if dry working is unavoidable, it is advisable to work shallow."

#### FREE PARLIAMENT.

A number of questions were dealt with by the Conference. The Secretary of the Advisory Board (Mr. G. G. Nicholls) was asked if it would be possible to have printed and circulated among the members of the Branches in the mallee districts east of the Murray forms on which they could, at the close

of each harvest, state the results obtained, the methods of cultivation, &c., which they had adopted, and the quantities of manure and seed used. He assured the Conference that the board would be glad to distribute such forms, because it recognised that the practice of submitting harvest reviews at meetings of the Branches was an excellent one.

#### SHOOT CUTTING.

The inquiry, "Is it advisable to cut shoots on fallow before harvest and again afterward, or to leave them until after the harvest and cut them only once?" was responsible for an animated discussion. Mr. Trowbridge said he had always avoided using the billhook or slasher as much as possible, and instead had utilised the firerake. Where it was necessary to fallow land with a large quantity of shoots on it these should be cut before and not after fallowing. Mr. McCormack and several others favored "cutting the shoots at all times, and keeping sheep." Mr. F. Norton (Geranium) was convinced that the best plan, where at all feasible, was to put on a heavy draught at the outset of operations and haul out as many of the stumps as they possibly could. That procedure would also result in a considerable percentage of the remaining stumps being weakened. Mr. Edwards (Pinnaroo) submitted that the shoots should be cut regularly every year, but burning was certainly preferable. Mr. Coleman introduced the subject of a mechanical shoot scorcher, and, at the instance of Mr. Norton, it was resolved to recommend the Advisory Board to suggest to the Government the advisableness of offering a bonus for a successful shoot scorcher. There was considerable diversity of opinion respecting the cropping of land with wheat for two years in succession after fallowing, although most of the speakers agreed that two or sometimes three or four successive crops could be taken off where virgin land was being dealt with. Several, however, were of the opinion that when two crops succeeded fallowing the second one should consist of oats.

"Can mallee land be successfully farmed with the disc cultivator?" was a most productive theme. Some delegates said the disc possessed a great advantage in that it assisted materially to reduce the number of shoots, but others were equally convinced that the share plough was the better in every respect. Mr. Eime (Lameroo) said he had always employed the share plough, and during the nine years he had been farming from mallee his average yield had been 14bush. to the acre.

"How to eradicate 'lignum' bush?" was answered by Mr. Johnson (Parilla), who advocated "fallowing the ground, cutting the bushes off close to the earth, and running sheep to eat off the young shoots in the summer."

#### TREES AND TREE-PLANTING.

Mr. Gill answered a number of questions concerning the merits of different kinds of trees, and how to plant them. Sugar and blue gums, he said, were

both good from the timber standpoint. Sugar gum piles had lasted for 30 years at Port Adelaide, and posts had remained serviceable for about 40 years. Railway sleepers after 22 years were reported to be "still going strong." Sugar gum timber had been frequently unjustly condemned for the reason that it had been cut when too young, or at the wrong time, and had not been properly seasoned. The blue gum was absolutely unrivalled in Australia for felloes, naves, and other wheelwright purposes. Both classes of trees, comparatively speaking, did well in the Pinnaroo district, and the seasoned timber from each was of about the same weight. It was always well to prepare thoroughly the holes intended for the reception of trees, but if horse manure was used it should be absolutely decayed, and be placed in the bottom of the holes. As a rule, however, forest trees did not require manure at all. What they needed, particularly in the earlier years, was plenty of moisture.

#### WORKING LAND WHEN DRY.

"Does the Director consider it wise to continue fallowing while the land is dry, or would he advocate the suspension of operations pending rain?" In reply to this question, Professor Perkins said it was generally agreed that to work the land wet was, under all conditions, the best plan, and he certainly agreed with that view. In dealing with the specific inquiry he thought the most satisfactory procedure would be to tell them what was done on the Roseworthy College farm, even though the conditions there were not quite what they were in the mallee country east of the Murray. At the College they had some very heavy land, and also some that was light, as well as a certain area traversed by sand ridges and limestone. Seeding having been completed, one must get ready some land for the next year's crop. Personally he had never been able to see why they should wait for rain if it was at all possible to plough. He was less afraid of ploughing land dry early in the season than he would be later. He would not mind ploughing dry in the winter, because he would expect plenty of rain, which would work down and consolidate the soil. At all times, however, he would sooner work heavy land dry than light land. If proper implements were available, the land should be well worked down after the ploughing. He quite admitted that if light land was ploughed dry, and deeply at that, and the subsequent rain was not sufficiently heavy, they would not be able to consolidate the soil, however much they might work it. Where the circumstances rendered such a course feasible, he would select the heavier land to work dry, and leave the light land until the rain came. He recognised, of course, that the difficulties in the mallee were greater than they were at the College. What they decided to do must depend upon the area to be fallowed and the number of teams they could put into the field at a time. Still, if early in the season, he would plough dry. If he could possibly avoid doing so he would certainly not plough dry in September. Where such dry working had to be done it was

essential to use a very heavy roller afterwards. The rollers generally used were altogether too light, and therefore were not nearly so effective as they ought to be in securing the desired consolidation of the seed bed. Cultivation before seeding, whether wet or dry, should certainly be shallow.

#### FEEDING OFF THE CROPS.

"Is it advisable, in a dry season like the present, to feed off crops?" was the second question which required consideration. At the College, the Director explained, feeding-off experiments had been conducted during a period extending over four years. When he inaugurated the investigations he had a rather favorable idea of what the results of feeding off a crop of wheat were likely to be. In the end, however, he had been forced to the conclusion that the enthusiastic advocates of the practice were generally men who had sheep to feed. No doubt in certain circumstances if the sheep were starving they might have to choose between them and the crop. But in the experiments referred to he had never been able to say that there were any distinct advantages in feeding off crops except when they were badly grown or, through being over rank, were inclined to lodge. In seasons such as the present, except in cases where the crops had germinated unevenly, or showed rank growth, he could not agree that feeding off would do a crop any benefit. He would sooner roll it, especially if the crop appeared to be rather weakly, and the seed bed was at all hollow. In every district there was a limit regarding the time when a crop would be safely fed off without injuring it. At Roseworthy if they fed off a crop later than the first week in July they ran a big risk of reducing the yield by a good many bushels per acre. As the Pinnaroo district was considerably later, however, the local farmers probably could feed off much later, but in average circumstances he thought the middle of August was far too late.

#### EXPERIMENTAL FARMS.

The third and final inquiry was, "Is the Director in favor of the operations of experimental farms being extended?" In reply, he agreed that the work of the farms might be extended in those centres. When a farm was established in any district, it was there primarily for those in the immediate neighborhood in the sense that it could be utilised to test any questions in which the farmers were interested. From the standpoint of the State, however, he thought it was possible to have too many experimental farms. In preference to increasing the number of those establishments, he favored the inauguration of additional experimental plots on selected farms in different parts of the State, to be properly managed and conducted under the direct supervision of the local Branches of the Agricultural Bureau. The owners of the farms, of course, would be well remunerated for the work required of them. In isolated districts like Eyre's Peninsula and the West Coast, one or two experimental

farms were undoubtedly necessary as centres for the solution of certain problems and the dissemination of information, but the great difficulty about the experimental farms was that through them there was accumulated a capital expenditure which was a constantly increasing charge to the State, and which it was extremely hard to keep down. On the other hand the farmers' experimental plots represented merely an expenditure from year to year which could be stopped whenever desired. He was confident that almost, if not quite, as good and useful work could be accomplished by means of the latter as with the aid of the Government farms, granting, of course, that they were managed by thoroughly capable and conscientious men, and were effectively supervised.

### MORNING SESSION.

#### SHEEP ON THE FARM.

Mr. R. L. Beddome (Parrakie Branch) delivered a paper on this subject. The agriculturists in this and other newly opened districts, he said, would be well advised to make provision for increasing the livestock on their farms, even though that policy might involve placing smaller areas under wheat.

In those cases where the majority of them had confined their energies to wheat-growing, the difficulty of working their land successfully had been made manifest during the present run of dry seasons. The two main causes of that lack of success, and which might even threaten the prosperity of the district, he considered to be undue preponderance of wheat and lack of timely rains. The latter factor was unfortunately beyond their power entirely to combat; but its effects could be minimised and to a surprising degree overcome by systematic fallowing and good cultivation generally. Crops on good, clean, fallowed land had grown remarkably well throughout the district during the last two or three years, although the winter rains had been exceptional only by their absence. However, as any dry working of the fallows had the effect of endangering the subsequent crop by rendering it more liable to the attacks of takeall, it was necessary to run stock on them occasionally to keep them clear of weeds. Thistles and many other weeds flourished amazingly on fallowed ground without any rain, but it was inexpedient to be continuously cultivating and harrowing in spring and summer. As weed destroyers, sheep were by far the most effective of any farm stock, as they could be run on the fallows whenever conditions were favorable, and would keep them clean. Sheep or cattle, however, if run on a sandy fallow, when the surface was dry, were apt to cut the ground up unduly, and render it liable to drift; but when the ground was moist any stock, and

sheep particularly, had the opposite and desired effect of packing and consolidating the soil, which was thus of great assistance to the subsequent crop.

Many farmers had learned by experience of the danger of "carrying all their eggs in one basket." The wheat crop might, from one cause or another, be a failure, and in such a case the presence of a small flock of sheep on the farm would be doubly advantageous. Apart from the direct benefit, many a crop in the district would have yielded much better than it had if it had been fed down by sheep at a critical period. This year many early wheat crops had distinctly benefited through having the sheep on them; whereas many others left untouched had run up and were coming out in ear unseasonably. The principal objection to keeping sheep in new mallee lands was, of course, the absence of natural feed, and consequently the limited carrying capacity of a farm. That constituted a real difficulty, as the expense of sheep-proof fences, protection from wild dogs, watering facilities, &c., would be prohibitive for the purpose of keeping a mere handful of sheep. For the sheep to justify the expense and trouble incidental to them, and to be of much value on the fallows, it was necessary to have, say, from 200 to 300 at least. No doubt many farms in the district could run that number or more in comfort without having to provide food for them, apart from an occasional run on the crop.

#### SUCCESSIVE CROPPING.

Most farmers in the mallee found it necessary to crop their land almost continually for the first few years for the purpose of killing the shoots; and that persistent wheat-growing had resulted in numerous instances in the appearance of takeall, general impoverishment of the soil, and a corresponding reduction of wheat averages. The best method of killing the mallee without unduly impoverishing the soil and of keeping the paddocks free from takeall was undoubtedly to grow oats. If a crop of oats were grown after two successive wheat crops, and the stubbles turned, very few, if any, shoots would remain. Of course, the carrying out of such a practice involved the sowing of a considerable area of oats each year—in fact, an area equal to that of the wheat crop. That policy also involved the strong probability of losing a fair proportion of the grain through rough weather at ripening time. Then there had to be considered the difficulty often experienced of obtaining a ready market for the oats when harvested. He suggested, however, that the indirect value of the crop in connection with the feeding and fattening of sheep was sufficiently considerable to outweigh any loss in the direct return from those causes. If a farmer had a good-sized area sown to oats early in the autumn the crop began to pay its way so soon as the sheep were running on it. This season, when the rainfall had been far below the average, most of the early sown oat crops in the district might carry a fair number of sheep without harm to the crop for another month,

at least. When it became time to move the sheep out of the crop they would probably be needed on the early fallows for the purpose of cleaning off the weeds. Assuming that a considerable acreage of oats was sown the previous year, one could rely with tolerable certainty on having really good sheep feed by that time in the resulting self-grown crop.

#### INDIRECT GAINS.

Thus, by combining sheep with oat cultivation, even supposing the oat crop to have failed to show a directly profitable return, indirectly it would have more than justified its production. Unless farmers made the mistake of overstocking, their sheep should be in excellent condition at harvest time, and by having a small paddock of peas, there should be no difficulty in placing a good proportion of the sheep in the market in prime order. If that result were achieved it would have the twofold advantage of returning the greatest profit from the sheep, and of reducing the number of stock on the farm at the period when feed was scarce, and when the presence of many sheep on the lighter lands was undesirable. Fat stock of all kinds were likely to find a ready market, as the demand for meat from American and European markets was increasing, and for that reason he advocated the selection of good, large-framed sheep for the farmers' flocks. Lamb-raising was rather hazardous in many parts of the district owing to the prevalence of wild dogs; but given immunity from that pest, lambs thrived, and, keeping meat in the forefront, one would do well to breed from six-tooth or full-mouthed Merino ewes sired by Lincoln or Shropshire rams.

#### TESTS AT ROSEWORTHY.

Professor Perkins congratulated Mr. Beddome upon the sensible and pithy character of his paper. At Roseworthy they had devoted a great deal of attention to the subject of "sheep on the farm." Records showed that the carrying capacity of the place during the last seven years had averaged one sheep to the acre over the whole of the farm, more than two-thirds of which each year had been under crop and bare fallow. He did not suggest that it was advisable to stock land to the utmost of its capacity; neither did he agree with those who favored, like the squatters, keeping the number of stock down to the limit of the country in the worst time of the year. He had always held that if they did that they would not reap anything like the full benefit they might. The time would come in the mallee country when they would have a better class of natural pasture than they now possessed, and one of the principal factors in bringing that about would be the use of superphosphate on a larger scale than they were generally accustomed to employ. It would interest them to learn that at Roseworthy on barley stubble on light limestone soil of the character of that between Tailem Bend and the ranges, in a satisfactory year, they had carried something like four sheep to the acre during

the whole of the year. Reference had been made to the oat grain shaking out, but he could assure them that sheep would pick up the greater part of that readily, and the remainder would germinate and make one of the finest pastures he was aware of.

#### BARLEY.

He strongly favored the growing of barley as a crop that could be fed off. If it got a fairly early start, it would make far more rapid headway, would give earlier feed, and would stand feeding down better than any other cereal. He would not feed wheat down later than the first week in July, but barley sown early could be safely fed down late in July without much influence upon the ultimate yield. When prices for grain were low it would pay better to market on the hoof than in the bag, and he was thoroughly convinced that oats could be fed to sheep profitably on the basis of the recent market rates, even at 2s. a bushel. The cost at that figure would work out at not much more than 1d. a head a day. Barley, however, was undoubtedly the cheapest grain that could be fed to sheep. He did not see why in that district they should not obtain as much as 50bush. of barley to the acre in a good season. He advised them, for feeding purposes, to grow the six-row Cape barleys. No other cereal required less rain than barley, which was the best resister of drought, and ripened three or four weeks earlier than wheat. Oats, on the other hand, were distinctly a wet-country cereal. He was pleased that the local farmers recognised that the future of the farming industry was bound up with sheep, and confidently expressed the opinion that the sooner they could get on to them the sooner they would obtain consistently good returns from their land.

#### VETERINARY CLUBS.

The Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.) in an address, dealt with the formation and working of veterinary clubs. In the main outlines the working of a veterinary club was similar to that of a medical club, he said, but in detail there were divergencies which demanded that it should be treated on its own merits. There could be no two questions as to the desirability of having qualified veterinary aid within easy call. In a young country, only freshly settled, it was hardly likely that a man who had spent many years and £1,000 or more on his education, would choose a district like that to settle in speculatively. If he did he probably would be a young man out for experience more or less at his client's expense, or, what was worse in South Australia, owing to the lack of a Veterinary Surgeons Act, he would be a quack who made up for his want of skill by a superabundance of bounce.

#### HEAVY MORTALITY.

The normal death rate of stock was about 4 per cent., and a score of veterinary surgeons in a district would not prevent that. The death rate in

that particular locality was far higher, and a resident veterinary surgeon would assure them against the difference (say 8 per cent.). That not only covered their mortality loss, but left them with a profit of 4 per cent. Leaving the actual money aspect of the matter for a moment, three factors required preliminary consideration—(1) The district to be covered. (2) The working committee. (3) The terms of contract. Considering the present and soon to be increased means of communication, the district might be a fairly wide one, say, seven miles beyond Murrayville on one side and Geranium on the other, with the ordinary settled boundaries on either side, the line centre at Pinnaroo. The working committee should be representative, but above all things small. The members to all intents and purposes would be the trustees of the fund, and he suggested a doctor, a banker, and a solid farmer as ample to deal with the matter. The doctor would have a certain amount of knowledge of the difficulties of the work and sympathy for the veterinary surgeon. The banker would take a cold-blooded financial view of matters, holding the balance even, while the farmer would critically judge the results of the work. Working for the committee should be a secretary and collector, who might be one or two persons, but on them would depend the success of the scheme as much as on the veterinarian, whose avocation on account of irregular hours and work would prevent him attending to the necessary details of book-keeping with the regularity they required. All he should be asked to do would be to furnish the necessary details to enable the records to be compiled and the books kept right up to date.

#### SALARY.

The fund should be not less than £1,000 or £1,200. They should not be alarmed at the figures, for probably not more than half would need to be called up, but there were three factors to be considered—salary, house, locomotion, and working expenses. The terms of contract, hypothetically, would be somewhat as follows:—The post would be advertised with appropriate baits in the way of salary and facilities; likely candidates would be chosen for interview, at which it would probably be well to have the assistance of an independent expert. Qualifications and experience having been satisfactorily proved, would come the question, "Should the candidate be married or single?" From his own experience a wife was a very valuable asset in the successful working of a practice. Next came the matter of salary. Brains have a price, and to get them they must pay that price—£300 to £500 a year should obtain the article they required. Probably they would get a better return at the higher figure than the lower. It was guaranteed to the veterinary surgeon, and there were two main ways of raising it—by a poll tax on stock, or by a subscription either of a fixed sum by each subscriber or in ratio to the stock owned. The second was the more workable, and things were much

simplified if a regular subscription could be agreed upon. There were pros and cons in regard to private practice or extra payments for major operations and so forth. They were worthy of attention, but in his own experience the club worked best when a reasonable salary covered everything. If the veterinarian depended for a part of his living on non-club members they would naturally claim a large share of his attention, and with the usual fatalism of the farmer he would not join the club if he could avoid it, knowing he could get the expert. If, however, the latter attended on only club members, the club would become financially strong, and as it grew provision could be made to increase the salary. Thus both sides would be stimulated to do their best. There was the question of frivolous calls. A man of experience will be able to deal with them on their merits, but if necessary the committee could deal with complaints from either party, and suggest or direct.

#### TENURE AND HOUSING.

Next came the length of tenure. This should not be for less than three years, otherwise they would secure only birds of passage seeking experience. On the other hand a longer term might bind the committee in some undesirable way. If the veterinarian should not be quite what was wanted he could be borne with for three years, and if he was what they did not want to lose the three years could readily be extended. Relatively to the question of housing, a house was a good asset for the club. A yard, with a crush pen and a sick box or two, will not be money lost. Respecting locomotion, in most districts let the club provide a motor; but on the whole here, he would prefer a light buggy and pair of strong ponies and a good saddle horse with a sulky to fit. The train would carry the veterinarian to the outlying parts, and owners could transport him from and to the station more readily than the motor could travel in some of the country he would have to work in, while on occasion the club could hire a motor where advisable. Most of his own country work, when in private practice, was done with clients' horses that were one too many for their owners; but they must give the expert a man to look after things. When he had been on the box or in the saddle for 24 hours, as often he would have to be, and longer, with dispensing and booking awaiting him when he got home, it was only fair that he should be able to fling the reins to somebody else to attend to the horses that were probably as tired as he was. In addition, a great part of a veterinary surgeon's work required the assistance of a man who had at least some idea of what to do. A yearly pass over the line in the district would be an economy. Drugs, instruments, and kit should be the club's, and they would probably be surprised at the comparatively small outlay these would involve in a district of that character—probably £100 would cover them.

## SUMMING UP.

All work and no play made Jack a dull boy, so arrangements should be made for a *locum tenens* for three weeks or a month every year in the slack time. In conclusion, he advised—"Do not interfere with the way the man runs the practice, beyond a word of warning if socially he goes wrong. Remember you have chosen him as an expert, and he can tell you more about his work in five minutes than you could teach him in a lifetime; if not, you have made a mistake in your choice. However, 'art is long and life is short,' and your club has funds invested in work that the kick of a horse may incapacitate your workman from entirely, or a poke from a bullock lay him up for a time; so, as ordinary business men, insure his life and his limbs. The offices will load him up into class six, thereby showing what they think of the risks the man is taking for you. To sum up—Bring together a provisional committee; select your working committee; outline your district; estimate your income and the apportioning of the tax; decide details of salary, house, &c.; make known your terms; select your candidate; make a fair and square deal with him for whole time work; make things run as smoothly as you can; remember that he too is a man; discover that you have made one of the most profitable investments possible for an agricultural district."

General concurrence with the ideas of the lecturer was expressed by delegates, and it was decided to request the committee, which had been formed at Pinnaroo in order to draw up a working scheme, to give the various Branches the advantage of their deliberations.

Wheat Crop and Virgin Land, Pinnaroo.

\* No report received during the month of August.      † Formal report only received.  
 ‡ Held over until next month.

## ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

October 14th and November 11th.

## THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

### REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

#### UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

##### HOOKINA.

August 4th.—Present : nine members.

**IRRIGATION.**—Mr. P. Kelly introduced a discussion. Members considered sprinklers the best means of irrigation, as a great saving of water was effected by their use. The chief difficulty was to ensure sufficient pressure. It was generally agreed that the old method of "flooding" involved the use of an enormous quantity of water in some soils.

##### TARCOWIE (Average annual rainfall, about 15½in.)

August 5th.—Present : 25 members.

**POULTRY BREEDING.**—Mr. M. Murphy read a paper. He strongly advised artificial incubation as being more satisfactory than the use of broody hens. Prior to mating in July, August, and September, the male should have been isolated for some time, he said. The practice of mating pullets was unsatisfactory. The breeding hens should be carefully selected by means of the single egg test for preference, or by careful observation regarding characteristics, such as alertness, readiness to forage, &c. Birds disposed to cannibalism and egg-eating should be discarded. Shell grit, secluded nests, &c., should be provided. The incubator should be placed in a well ventilated room which retained an even temperature. The floor of the brooder should be covered with grit to a depth of lin., and an opening to a small run, enclosed with wire netting, should be made. Drinking vessels and ground charcoal were necessary. For the first 24 hours no food would be required by the chicks, but subsequently coarse oatmeal or finely-cracked wheat could be fed. An interesting discussion followed the reading of the paper.

##### WARCOWIE (Average annual rainfall, 12-16in.)

July 4th.—Present : nine members and two visitors.

**EXPERIMENTAL WORK IN NORTHERN AREAS.**—A paper under this heading was read by Mr. Telfer, and the following is extracted therefrom :—"For the last 35 years farmers have been cultivating these semi-arid lands with more or less success, and experience goes to prove that wheat can be grown successfully in seasons when the rainfall is not below the average. The unfortunate circumstance is that in seasons when the rainfall is below the average the crops are practically a failure and the farmer is apt to lose what little capital and stock he may have accumulated during the few years of prosperity. This is exceedingly disheartening, and unless something can be done to increase the percentage of seasons in which the cultivation of the soil proves to be a paying business, the whole of the areas outside of Goyder's line of rainfall must go back into larger holdings and become once more a sheep walk. Some will say the sooner the better—it should never have been taken away from the squatters, and if the record of the last 35 years represents all that can be done in the way of agriculture, I agree ; but does it ? When the land was first broken it was in most cases fallowed, and then cropped with wheat three or four years in succession before it was again allowed to lie fallow for one season. After this it was again expected to produce from two to four crops of wheat—always wheat—before it again came under fallow ; and thus, in each decade, our land has been

expected to grow seven or eight crops of wheat. This method has, to a great extent, been followed right up to the present time, and this without any addition to the soil in the way of manure. In my opinion this country has never been fully tested, and the time will come when it will prove capable of carrying a far larger population than it is at the present time. Practically nothing has ever been done in the way of experiment to prove whether something other than wheat can be grown, or whether the returns from wheat crops cannot be rendered more sure by different treatment of the soil; whether some manure cannot be used that will materially increase our yield, or whether other kinds of wheat, more adapted to our climate or soil than those that we are at present growing, are available; whether drought-resisting grasses or fodders that will enable us to keep more stock on the farms, and thus increase both our revenue and the fertility of our soil, exist; whether drought-resisting fodder trees can be grown to provide feed for stock in the driest seasons. All these things are in the bounds of what is possible, and even probable, and only represent some matters that should be tested. Now the question arises as to who is going to carry out this work. Will it be done by private individuals in connection with or independent of the Bureau? I am of the opinion that the matter should be taken in hand by the Government. The only way that anything of value will be accomplished is by the appointment of a fully qualified man to devote the whole of his time to the study of our conditions and the carrying out of such experiments as may be deemed advisable." Members generally agreed with the remarks of the reader of the paper.

**FALLOWING.**—In initiating a discussion on the relative advantages of early and late fallowing, Mr. A. Bairstow said it was necessary to take into consideration the cost of feeding the team, the amount of work required for after cultivation, and the ultimate yield. He preferred to allow the weeds to get a good start before attempting to fallow, and just about the time the weeds were coming into flower to plough the land to a depth from 3in. to 4in., turning the sod completely over. This not only destroyed the weeds very effectively, but in all probability it would only be necessary to cultivate once or twice subsequently. The ploughed-under vegetation also would have a sweetening effect on the soil. Another factor was that when the land was fallowed early a fair amount of feed was secured from it, and the team would be in good condition for the work. When early fallowing was practised it would be necessary to stable-feed the horses to a considerable extent. In addition subsequent cultivation would have to be more frequent to destroy the weeds, and there was more liability of the surface being worked to dust. For these reasons, and from the result of actual experience, he preferred late fallowing. Members were divided in opinion as to the best course to adopt, but generally agreed that it was a good plan to plough the ground lightly in the winter, then work it to a greater depth later on.

#### WARCOWIE (Average annual rainfall, 12·16in.).

August 4th.—Present: eight members.

**SHEEP FOR DISTRICT.**—Mr. C. Hilder read a paper. For this district he recommended the Merino, with a clean face and legs free from wool. Constitution was a most important point, and as usually the good years were in the minority, a moderate weight of fleece only should be expected. The best time for lambing was March, as the lambs were then better able to withstand the cold of winter. The ram should be big, plain-bodied, with open face, deep neck, free from crossbars, and with well-sprung ribs. Members agreed in the main with the paper.

#### WEPOWIE (Average annual rainfall, 13in. to 14in.).

August 5th.—Present: 11 members and six visitors.

**SELECTING FARM IMPLEMENTS.**—Mr. T. F. Orrock read a paper on this subject. He preferred a plough of medium weight. A sidelaid lever would be found of considerable advantage. Stump-jump harrows were most suitable, and the rib roller was becoming popular in this district. He referred at length to the different styles of harvesters, strippers, binders, drills, &c., and compared the advantages of each.

#### WILMINGTON (Average annual rainfall, 18·26in.).

August 5th.—Present: 12 members.

**WORKING EIGHT-HORSE TEAMS.**—Mr. Hannigan read a short paper in which he advised farmers, when working eight horses in a team, to have them four abreast. The four-horse swing should be of 6in. x 4in. hardwood. Backbands should be used on the hind horses. For the leaders he preferred leading traces

to *swingletrees*, and for draught he used a chain 3ft. long, attached to the hind horses' traces, with runners to keep them in place. Double reins should be used on the leaders, and it was a great mistake to work the horses too close. Mr. D. S. George preferred working eight horses abreast. Backbands could then be dispensed with. Mr. Zimmermann thought it necessary to attach a tug 18in. to 2ft. long to the chains of the hind horses. He preferred working the team with leaders. Messrs. Farrell, Pickering, and B. Jericho (chairman) preferred to work the horses abreast.

#### WIRRABARA (Average annual rainfall, 18.91in.).

July 11th.—Present: 24 members.

**AFFORESTATION.**—A paper on this subject was read by Mr. C. H. Curnow. With natural timber, he said, generally there was a good deal of worthless rubbish. This should be destroyed either by ring-barking, the wood subsequently being sold, or cut down and burnt on the spot. This gave the remaining timber a better opportunity of developing, and better grazing was secured. A good growth of young timber would generally result, especially with the eucalypts. Trees should be planted at least 16ft. apart. In discussing the subject, members agreed that generally forest trees were planted too close together to give best results.

#### WIRRABARA (Average annual rainfall, 18.91in.).

August 8th.—Present: 21 members and two visitors.

**PLANTING FRUIT TREES.**—A paper on this subject was read by Mr. W. R. Curtis, and the following is extracted therefrom:—"The ground intended to be planted should be cleared of all roots, stumps, and stones, and ploughed as deeply as possible, in the winter. It is a good plan to plough three or four rounds, leaving a furrow where the trees are to be planted, and then to go two or three more rounds, throwing out a furrow deeper and wider. By doing this it should be possible to plough about 18in. deep with a single-furrow plough where the rows should be. These furrows can be filled in by crossing once or twice with the cultivator or harrows. Care should be taken not to run these up and down hill, or the rain may wash out gutters. This method is better than digging holes, being quicker and cheaper, and it affords better drainage. One of the principal points to consider is the fence. This should be strong, as hundreds of young trees are killed by cattle and horses breaking them down and rabbits and hares barking them. Trenching or digging holes is unnecessary in rich sandy loam or any soil which is adapted for fruit growing. Position should be considered." In the discussion that followed, Mr. E. Pitman reported having visited one planter who was preparing his land by the use of explosives: this he considered very satisfactory on stiff heavy land.

**COOMOOROO, August 1st.—CO-OPERATION AMONG FARMERS.**—A paper dealing with this subject was read by Mr. W. Robertson. He referred to the difficulty of management of a co-operative concern, and thought the expenses in the cases of small communities would be prohibitive. He advised farmers to form themselves into small bodies of about 12 in number, each one in turn ordering and taking delivery of requirements, and distributing them to the other members of the body. This was being done in this district with satisfactory results.

**DAVENPORT, July 23rd.—HANDLING WHEAT IN BULK.**—In a short paper on this subject, Mr. Gosden drew attention to and gave instances of the waste which occurred in connection with the present system of handling grain. He contended that if the bulk-handling system were introduced, a good deal of this would be obviated. Whilst the initial expense to the State would be considerable, he expressed the view that this would prove a profitable investment. A saving in connection with bags would be effected, and he thought a better price would be secured by the producer for his wheat.

**MORCHARD, August 1st.—FARM MANAGEMENT.**—A paper written by Mr. F. Hawke, of Willowie Branch, was read. Mr. H. A. Toop advised members to read the reports in the *Journal of Agriculture* thoroughly. The secretary tabled a "wire worm," which, he said, did considerable damage to the seed before germination commenced.

### MIDDLE-NORTH DISTRICT. (PETERSBURG TO FARRELL'S FLAT.)

BURRA (Average annual rainfall, 17.82in.).

August 7th.—Present: 10 members.

**ENGINES ON THE FARM.**—This subject was dealt with in a short paper by Mr. G. R. Finch. He strongly recommended purchasing an engine for such work as chaff-cutting, woodsawing, grinding, pumping, &c. A 4-h.p. engine would be found capable of pumping water to a height of 23ft. without straining. Generally for farm work the oil engine would be found preferable to the petrol—it worked more evenly, and consequently its life was longer. It was unwise to purchase an engine that was recommended only by its cheapness. In the matter of oil, especially for the cylinders, only the finest should be used. The stationary engine would be found more satisfactory where most work could be done from one centre. This should be cleaned whilst still warm, and when not in use should be protected from the weather by a suitable covering.

CANOWIE BELT (Average annual rainfall, 20.04in.).

August 6th.—Present: 14 members and two visitors.

**FALLOWING.**—Mr. E. T. Daly read a paper on this subject. He strongly advised commencing ploughing with the implements in first-class order and the team in good heart. In this district the land should be ploughed to not less than 4in. or more than 6in. deep, across the previous year's ploughing, especially where a "V" shaped cultivator was used. The fallowing should be completed by the end of August, and harrowing should be immediately commenced. Weeds should be kept in check by sheep until the land was cultivated. It was unwise to cultivate the land dry; working after rain being much preferable. The writer strongly deprecated the practice of working the team from daylight until dark, but preferred to commence at 8 o'clock and work until sundown; giving the animals one and a quarter hours for dinner. Messrs. Dempsey, Carter, and Kirk agreed, the lastnamed gentleman strongly advising a small blacksmith's shop on the farm. Mr. A. Noll thought it better to fallow to a depth of from 3in. to 4in., according to the season. Land worked to this depth had, in his experience, returned the best crops.

LAURA (Average annual rainfall, 18.22in.).

July 3rd.—Present: 20 members and two visitors.

**DEEP AND SHALLOW CULTIVATION.**—Mr. E. G. Blessing contributed a lengthy paper on this subject. He said—"This is a subject upon which there always has been a great difference of opinion, some maintaining that ploughing to a depth of 3in. will produce a crop as good as 5in. or more. Of course, the depth of cultivation depends a great deal upon the nature of the land. For instance, in some localities where there is only a few inches of soil on limestone gravel, or where there is a shallow soil on a heavy clay bottom, it would be very unwise to bring the subsoil to the top. But these conditions are very rarely met with in our district. In fact, more than 90 per cent. of our wheat land could be cultivated to a depth of 6in. or more, which, in my opinion, would result in an increased yield of several bushels to the acre. One of the objections to deep cultivation is that it requires a lot more horsepower; but that would only apply to the first ploughing, as after the land is once deeply rooted up it will require very little more strength on subsequent ploughing. There is a special advantage in breaking up new or virgin soil deeply in the fact that the ground can be ploughed almost at any time of the year afterwards with very much less wear of ploughshares than if the land had been broken up shallow. Personal observation and practice during the last 50 years have convinced me that deep and thorough cultivation pays every time. In the Marrabel district, where I farmed for 18 years, two of the largest farmers always worked four horses in a double-furrow plough whilst all the others only used three, with the result that the former averaged from 2bush. to 5bush. more than the latter. It will be objected that in a drier district like Laura deep cultivation would be courting failure. Some time ago the Agricultural Department commenced experiments with the Campbell system of so-called dry farming at Hammond. The plot which was ploughed 4in. deep has for several years yielded about 2bush. less than the plot ploughed 6in. deep. I have seen at Baroota, in a dry season, a paddock where a number of rabbit burrows had been deeply dug and refilled, and the crop simply put in with the

cultivator with the result that the crop was scarcely worth reaping except where the rabbit burrows had been filled in, and there the wheat matured well. I have also experimented at Bangor with sorghum in a dry summer. The soil was dug to a depth of 10in., and where this was done the sorghum maintained itself splendidly, while on ground ploughed only 4in. or 5in. it almost perished." In the discussion that followed Mr. R. Lines said he had not secured the best results from deep ploughing. Mr. R. Cleggett said good results had not followed deep ploughing of black ground. He had had over 36 years' experience and was not favorably disposed to deep ploughing. The character of the seasons had also to be taken into consideration. Mr. F. De Silver said that while approving of the principle of ploughing deep when breaking up new land he did not favor it as a general practice. If fallowed it should be done early in the season. It was not advisable to stir up the black soil too much as it would break the subsoil. In his opinion deep ploughing once in five or six years was sufficient.

#### MOUNT BRYAN (Average annual rainfall, 15·81in.).

August 3rd.—Present: nine members and three visitors.

**FARM IMPLEMENTS, ETC.**—A lengthy paper dealing with different implements and machines used on the farm was read by Mr. Phillips. He referred to the necessity for exercising care and judgment when purchasing, and to the advantages of different styles of ploughs, harrows, cultivators, &c. The ribbed roller was mentioned as an excellent method of breaking down patches that were inclined to be lumpy. This did not set the ground as was the case with the smooth roller, but the ribs loosened the surface slightly. The rolling should be done early in the autumn, before seeding. A drill of about 15 hoes was most satisfactory. A lengthy discussion followed. Mr. Thomas advised ploughing in stubble in preference to burning, with which opinion members agreed.

#### NARRIDY (Average annual rainfall, 16·79in.).

Present: six members.

**PICKLING WHEAT.**—In introducing a discussion on this subject Mr. Satchell said that unpickled wheat came up more quickly and thickly than grain that had been pickled. In years like the present he advised sowing unpickled grain, taking the chance of the development of smut, as pickled seed was more likely to malt. Mr. E. Smart favored pickling the seed, as in the absence of this precaution there was a liability of the returns being very considerably reduced by the development of smut.

**POTATO-GROWING.**—The Hon. Secretary (Mr. J. Darley) said he had grown potatoes in this district for 30 years, and only on two or three occasions was the result unsatisfactory. He favored the Pink Eye variety, and advised planting between the middle and the end of July. He would not advise members to plant extensively, but the trouble of putting in a few for use on the homestead would be well repaid. Early Rose or Purple Eye had also yielded well in this district.

#### NORTH BOOBOROWIE (Average annual rainfall, 16·15in.).

August 5th.—Present: 14 members and 11 visitors.

**BREEDING LAMBS FOR EXPORT.**—A paper on this subject was read by Mr. W. E. Hannaford. He said—"The first thing to consider is the ewes that are most suited for the purpose and locality. We are quite safe in disposing of all pure-breds. Merinos are not good enough mothers, their milk yield being insufficient for the purpose; and it is impossible to buy pure-bred ewes of any English strain at a price that would warrant one doing so, so we must turn our attention to crossbreds. As far as I am aware, no one in this locality has tried any of the different crosses, and we are, therefore, somewhat in the dark and must be guided by experiences of other places. We are justified in passing all the Down crosses, as they are not sufficiently heavy cutters and do not make as large roomy carcasses as some of the others. We might, with safety, confine our attention to the Lincoln-Merino and Leicester-Merino crosses. Both make very useful ewes with large frames, and carry a profitable fleece, are good doers, and capital mothers. Of these the Border Leicester-Merino crossbred ewe will, perhaps, come nearest to our requirements. If possible, two and a half year old ewes off shears, as uniform as possible in shape and size, with a long straight back and well sprung ribs should be purchased. The ram should be pure bred and the best we can afford. The Shropshire or South Down will best meet our requirements. Early prime lambs catch the fancy prices, therefore, they should be ready by the end of July. When the rams have been taken out the ewes should be kept on good nourishing food and receive greenfeed occasionally to keep them healthy. A month before lambing they should be crutched, care being taken to handle them quietly. When from four to

six weeks old the lambs should be marked, and all dry ewes should be taken out to give the ewes with lambs more room. From this time until they are marketed the lambs must be pushed along as rapidly as possible. The breeding ewes should not become too fat; they should, therefore, be placed with the dry ewes and kept in good store condition for the rest of the season. On no account should any of these lambs be kept for breeding purposes."

#### NORTH BUNDALEER.

August 5th.—Present: 17 members and eight visitors.

**ANCIENT AND MODERN FARMING.**—A lengthy paper under this heading was contributed by Mr. Pollard, who dealt with the development of agricultural practice from the early days of farming. The effects which had followed the invention of the stripper and the general adoption of application of superphosphates to wheat lands were mentioned.

**SHOEING HORSES.**—Mr. Burgess read a short paper. He advised members to refrain from putting hot shoes on the hoofs of their horses, and strongly deprecated the practice of rasping down the feet. Members generally agreed. Mr. Neill thought that the practice of leaving shoes on young horses for too long resulted in contraction of the heel.

#### PORT BROUGHTON (Average annual rainfall, 14.44in.).

July 31st.—Present: 10 members and one visitor.

**WHEAT GROWING.**—Mr. Dolling initiated a discussion on this subject. He advocated cropping every third year. Fallowing should be done to a depth of from 2in. to 3in., and be commenced early generally, but in very sandy land it paid to leave it until August or September, so that spring cultivating would not be necessary; consequently there would be less drift. Grass land should be ploughed after the first autumn rains, and strips left along the fences to prevent drift. He would skim plough first, then skim again in May, and work again finally before the drill. He used one bag of super. to every two acres, and preferred shallow seeding. In the discussion that followed Mr. A. J. Fletcher said that a little drift over the flats was very beneficial. Mr. Hill thought that 60lbs. of super. per acre sufficient, while Mr. J. H. Fletcher (Hon. Secretary) recommended using 100lbs. Mr. T. E. Pattingale would use the cultivator more and the plough less, and thus discourage the drift.

#### PORT GERMEIN (Average annual rainfall, 12.84in.)

July 18th.—Present: nine members.

**SOIL ANALYSIS.**—Mr. Hackot contributed a paper in which he dealt with the chemical constitution of soils. He referred to the researches and discoveries of Sir. H. Davy, and the important bearing these had had on soil chemistry. Many interesting chemical facts were given. A number of members took part in the discussion on the subject.

Mr. Pearce exhibited a model dog-proof fence. Members evinced much interest in this.

#### PORT PIRIE (Average annual rainfall, 13.21in.)

July 4th.—Present: nine members and one visitor.

**WASTE ON THE FARM.**—Mr. Hawkins delivered an address on this subject. He referred at length to the waste of cocky chaff and straw, which would have proved very valuable fodder for stock during the periods of shortage, such as had just been experienced. He strongly deprecated the practice of keeping old and useless stock on the place, as the feed they consumed could be utilised to much better advantage if it were given to better animals. Fowls which had access to the hay stack caused a considerable amount of waste; poultry to be kept profitably should be housed and thoroughly cared for. Weeds should be dealt with in the early stages of growth. Mr. Munday endorsed the remarks of the speaker. At one time he had secured considerable profit from poultry, but owing to the trouble caused by foxes he had relinquished poultry-keeping altogether. Mr. Eagle advised careful attention to the stack of hay, and Messrs. F. Johns, J. Krieg, Kirchner, and the Chairman (Mr. D. L. McEwin) also took part in the discussion.

#### WHYTE-YARCOWIE (Average annual rainfall, 13.91in.).

July 21st.—Present: seven members.

**THE COST OF PRODUCING WHEAT.**—Mr. S. F. W. Robinson contributed a paper in which he set down the various expenses incurred in connection with the production of wheat. He pointed out that the relative cost per bushel in a 30bush. crop was much lower than that of a 10bush. crop on the same land. The expenses to be allowed were:—Ploughing, 5s. per acre; harrowing twice, 1s. 6d. per acre; cultivating, 2s. per acre; harrowing, 9d. per acre; cultivat-

ing after harvest, 2s. per acre; drilling, 2s. 6d. per acre; harrowing, 9d.; seed, 4s.; manure, 2s. 6d.; rolling or harrowing after crop was up (preferably the former), 6d.; harvesting or binding, 3s.; bags, sewing twine or binder twine, say, for 15bush. crop 3s. 6d.; cartage for a distance of, say, from five to six miles, 2s.; which would bring the cost up to, approximately, 30s. per acre. This meant that a return of practically 10bush. per acre was necessary to cover expenses. In addition to those enumerated, there were the matters of rent, rates, and taxes to be taken into consideration. The consensus of opinion of members was that the writer of the paper had, if anything, underestimated the cost of production.

#### YONGALA VALE (Average annual rainfall, 13in. to 14in.)

August 3rd.—Present: 19 members and two visitors.

**STOCK-RAISING.**—Under the title of "Are Farmers Making the Best of Their Opportunities," Mr. A. Jamieson read a paper, in which he raised the question as to whether farmers could not more profitably occupy their holdings by giving more attention to stock-raising. Too frequently, he said, the class of stock to be seen on farms was not the most suitable, and often quite useless animals were kept. He also made a strong plea for more intense cultivation. A lengthy discussion followed. Members agreed that in the near future, as population increased, it would become necessary to produce more from the land than was secured at present.

**BELALIE NORTH, August 8th.**—**CO OPERATION AMONGST FARMERS.**—A discussion on this subject was initiated by Mr. Bladdon. Various members expressed their views on the matter. [This subject will be dealt with at the Congress of the Agricultural Bureau in September. The report of this gathering should be read for any further information desired.—Ed]

**GEORGETOWN, August 8th.**—The programme took the nature of a question evening. In reply to inquiries Mr. J. C. Myatt recommended setting eggs between the months of August and October, and in some cases November. The best all-round fowl for sitting, he thought, was the Buff Orpington, and White Leghorn hens that became broody should be destroyed. Members generally agreed that the best depth to cultivate soil in dry seasons was between one and two inches.

**MOUNT BRYAN EAST, August 1st.**—**SHEEP.**—The matter of the most suitable sheep for this district was discussed at some length. Some of the members reported that they had secured good results from crossbreds, but the majority favored the Merino. The seasons were uncertain in this district, therefore it was unwise to depend on fattening crossbred lambs.

**MUNDOORA, July 25th.**—**FALLOWING.**—A paper on this subject was read by Mr. C. H. Button, in which the practice of early summer fallowing in most soils was recommended. An interesting discussion followed the reading of the paper.

**WHYTE-YARCOWIE, August 3rd.**—**CO-OPERATION.**—Papers on this subject were read by Messrs. G. McGregor and F. H. Lock. Members discussed the matter at length.

### LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

#### BALAKLAVA (Average annual rainfall, 16.03in.)

August 8th.—Present: 10 members.

**CLEANING AND MARKETING WHEAT.**—In an address dealing with the question of improving the market sample of South Australian wheat, Mr. R. S. Goldney said the farmer received no encouragement to clean his grain. He grew a variety of wheats, which were mixed when sent to the merchant for shipment, yet certain wheats were possessed of much better milling qualities than others, and merchants had said that they would be prepared to give better prices for the better qualities. Unfortunately, those wheats which were the best milling were not the heaviest yielders, whilst the poorer varieties yielded more abundantly, and the farmer preferred to grow the wheat

which gave him the best price per acre. Recently, in London, the system of bulk handling was condemned in preference to receiving the wheat in bags. The elevator system would be a very costly affair, and could only be established in a few centres, where wheat would have to go before being sent to England. That would mean more carting or shipping, and, therefore, increased cost. The time had not arrived in South Australia for the inauguration of the system. The high standard of Australian wheat, however, should be maintained by farmers taking greater care in cleaning their wheat. Though that would mean a little more work, it would repay in the maintenance of the reputation which their wheat had in the markets of the old world. Mr. Tuck thought they had not paid sufficient attention to cleaning their wheat. He favored bulk handling, although he did not think the time had arrived for the introduction of the system. Inquiries should be made concerning it. Mr. Gleeson agreed that the time was not ripe for the introduction of the bulk handling of wheat. However, bridges for weighing their wheat should be provided. Mr. Uppill thought the Government should try the elevator system on a small scale by erecting elevators at Port Adelaide. Mr. Spillane thought if they graded their wheat better they would secure a better price for it. The chairman (Mr. H. L. Twartz) mentioned that the trouble of mallee leaves found in wheat reaped off land on which the mallee had sprung up could be overcome by allowing the wheat to lie for a few days, until the leaves were dry, when they could be cleaned out with the chaff.

#### FREELING (Average annual rainfall, 17.85in.).

August 12th.—Present: 11 members and one visitor.

**RED RUST.**—Mr. E. Roberts read a paper, in which he described the life history of this parasitic plant. He explained that the familiar red patches on the flag of wheat consisted of thousands of spores on stalks rising from the surface of the leaf. These, when ripe, were scattered by the wind, and on coming in contact with the plant, under favorable conditions of moisture and temperature, germinated and emitted long tubes, which, on reaching the breathing spores of the plant, developed vegetative organs. These produced new spores. When the straw began to whiten, the affected spots became somewhat black in color, and below the stem of the leaf was found a black powder consisting of spores of a different shape and color, which remained in the straw and germinated on the return of warm weather. They produced smaller spores which were distributed to a host plant, which in Europe was an ornamental shrub known as the Barberry plant. A further generation of spores was produced, which gave rise to the red rust on wheat.

#### JULIA (Average annual rainfall, 18in. to 19in.).

July 11th.—Present: nine members and four visitors.

**HAY GROWING.**—Dealing with this subject in a paper, Mr. J. Dunstan said:—"When sowing a crop for hay give a liberal seeding, say, 1½bush., to almost 2bush. in the case of Le Huguenot, which will not be so coarse when sown thickly. Put on 1½cwt. to 2cwt. of super. Marshall's No. 3, King's White, Dart's Imperial, Bluey, and Le Huguenot are suitable hay wheats, and Algerian is one of the best oats for this district. Le Huguenot must be chaffed; the same applies, to a certain extent, to King's White. The difficulty in regard to this is the beard. I think it a good thing to cut this variety before the beard dries up. This gets rather hard and prickly if left too long before cutting, and Le Huguenot on the other hand, has in my experience a tendency to cause animals, especially old horses, to scour, if cut too green. I should leave it until the grain was almost full and the flag beginning to dry before cutting. King's and Algerian oats make a good hay mixture, and they cut a good chaff also. Le Huguenot and Algerian oats, either grown together or separately, and mixed at the cutter, are also good. I should cut oats when the grain is quite full and turning yellow, as the straw then contains a good percentage of sap, and the grain would be almost, if not quite, matured when the hay was dry and ready to stack. It should then cut a nice chaff if mixed with green wheaten hay. Dart's Imperial is a good variety for hay. It grows tall, with a very green straw right to the ground, and is very sweet if cut and cured properly. Marshall's No. 3 is a good hay variety also. The straw is not quite so green as Dart's Imperial, but it is very sweet, and relished by the stock. Marshall's, Dart's, and Bluey are suitable to feed long to horses, but even these varieties should be chaffed for aged horses or those whose teeth need the services of a dentist. Federation is not considered a very good hay wheat, and, in my experience, I prefer the other mentioned varieties. In regard to stooking and stacking, if the sheaves

are thrown together anyhow in this windy district a lot of them are blown over, and if we should have showery or dewy weather all sheaves lying down become musty and discolored in the centre. I have seen a lot of hay near Adelaide stooked with the sheaves flat on the ground, and built up like a pyramid. I have tried the same style here and find it to be a failure, as the bottom sheaves were almost in every instance musty and mouldy; this would be poor stuff on which to feed horses. Therefore, I prefer stooking hay upright in stooks of, say, 12 or 15 sheaves. It should be ready to stack in from 10 to 14 days; wet weather, of course, excepted. Put plenty of straw on a wood or stone foundation under the stacks, which will keep the bottom sweet. Do not build stacks too wide, as a wide stack is inclined to get a hollow back, and the outer sheaves dip inwards. It would pay the larger farmers to build iron sheds for their hay, but the small landholder had perhaps better thatch his stacks properly, as the outlay in shed building would be considerable. Nevertheless, an expensive shed is preferable to wasting good hay year after year in a country like this, where hay is so valuable."

MALLALA (Average annual rainfall, 16.88in.)

August 3rd.—Present: 15 members.

**PREPARATION OF SOIL FOR SEEDING.**—A paper dealing with this subject was read by Mr. W. Curnow. He stated that fallowing should be commenced as soon as possible after seeding to secure the advantage of the winter rains. The ground should be ploughed about 4in. or 4½in. deep, but where a farmer was working the same land for a number of years he advised a variation in the depth of working. The ground should be well ploughed to a depth of about 5in. the first year, thus enabling the roots to get down to moisture and turning under surface rubbish. The following season the land should be ploughed to a depth of about 4in. to 4½in., and for the third fallowing the cultivator should be used, working at about 3½in. to 4in. deep. The next season it should be ploughed deep again. Thus the land would receive one deep ploughing every six years. Generally fallowing should be finished by the end of August to preserve as much of the winter's moisture as possible, besides giving the weeds a chance to grow, they could then be more effectively destroyed during the summer months than at the following seeding time. Sandy soil could be fallowed later than August, as the conservation of moisture was not so important, and the sand was not so likely to drift as if ploughed early and beaten down smooth by the winter rains. After ploughing, harrowing should be proceeded with to break down any rough clods and pack the land together to ensure moisture being retained and to cover any seeds that had not germinated before the fallowing. This should be done either a few days after ploughing or if left for a few weeks, after a rain, as any rough clods would need softening again. All fallow should be cultivated at least once before harvest, and harrowed down again soon after rain. He did not hold with working the land while it was in a dry powdery state if it could be avoided. This allowed what little moisture there was to escape, and tended to encourage the development of takeall. The harrows should follow each cultivating, as the soil would then hold the moisture much better, and it also allowed a more uniform depth of working than would be the case if the wheels occasionally ran in the hollows and sometimes on the ridges left by the previous cultivating. Most fallow needed cultivating between harvest and seed time, but if the ground were clean this would not be necessary, as the harrows had an equally good effect in the direction of conserving moisture, except in very stiff land which might run together and set. Seeding should generally be commenced either in April or May, according to the season, but it was better to wait for a fair rain (unless the season was an exceptionally late one), thus possibly destroying another lot of weeds and giving the seed a better chance to germinate satisfactorily. For working the soil at this time of the year, he said, the chisel tine harrows would be found most suitable; but where it was necessary to cultivate it should be done as shallow as possible, the maximum depth being about 2in. The seed should then be sown down on the firm bed. A few days after drilling it would be advisable to harrow the ground (crossways for preference), as this would kill more weeds, but where it was clean, and the seed was deeply sown, this might be omitted. Soil of a light chocolate nature should be worked with disc implements—these packed the land closer, thereby retaining moisture. In red clay land it was not wise to use disc implements, as land of this nature, being naturally closely packed, was more likely to set hard after a heavy rain. Mr. Nairn believed in cropping every second year, as the writer of the paper advocated. He favored the idea of cultivating shallow before the drill, and would plough to a depth of 3in. only. Mr. Arnold agreed with the paper on most points, but did not approve of deep ploughing. Cultivated fallow had sometimes paid best. Mr. K. Oliver agreed with Mr. Curnow's remarks. Mr. Lindsay thought fallowing should be worked more with scarifier harrows in preference to the cultivator.

## NANTAWARRA (Average annual rainfall, 15-90in.).

August 6th.—Present: 10 members and five visitors.

**FALLOWING WITH THE CULTIVATOR.**—Mr. F. J. Sutton read a paper, from which the following is taken:—"Fallowing by means of the cultivator, in my opinion, in this district is just that which is required. The cultivator will break and pulverise the land quickly to enable the first rains to soak into the soil to start the weeds early, and very often will more than compensate for the early working by the feed produced. Taking the case of a cultivator and plough working side by side, the plough is working to the depth of 4in., and is turning two-thirds of the grass, straw, weed seeds, small stones, &c., into the bottom of its furrow. With the rainfall of this district this rubbish will not rot within a reasonable time, and while this is lying there it is impossible to conserve the moisture. It must be brought to the top and its place given to the fine soil. Experience teaches that the earlier we get our fallowing done the better. When the cultivator is used, the first working is done very quickly, stirring well the top of the land, thus gaining the benefit of the first rains. The more frequently the land is gone over the greater the amount of moisture conserved. The soil is worked to a very fine tilth from the commencement, and needs no harrowing to break the clods and level the work after, as is the case after ploughing. The cultivator has an advantage over the plough owing to the pointed shape of its share. It finds its way in among the stumps and stones, where the plough share will not penetrate. Nature has put the best wheat-growing soils on top, and it is possible to make the land even more productive with only a very moderate rainfall by working the land to a much finer and more compact seed bed. It is here that the cultivated fallow will have the desired effect. Mr. R. P. Uppill said it was essential that rubbish, weeds, horse manure, etc., should be ploughed in to provide humus. In a wet season the growth of weeds would prove too great for the cultivator to cope with. It was also necessary to plough up the soil to allow light, air, and heat to sweeten it. He considered the plough the best implement to use for fallowing under present conditions. Mr. A. F. Herbert believed it to be a good idea to run the cultivator over all the land to be fallowed, and so get an early germination of weeds; then plough to the usual depth. Mr. Sleep considered that the rainfall was not high enough to rot much of the rubbish ploughed in. For light land he thought the cultivator would do as well, if not better, than the plough, besides being quicker. Mr. Smith said the work was not done so quickly as one would think, as it was necessary to let the cultivator into the ground, and this required more horse strength. Through fallowing with the plough in the present dry seasons the grass seeds became buried too deeply, and dirty fallow resulted. He agreed with the paper in regard to the superiority of the cultivator shares over the plough shares for working among stones, &c., and also in respect to the cultivator fallow allowing the early rains to enter the soil. Mr. G. Underwood preferred to use a skim plough with which he could plough 13 acres a day to a depth of 2in. or 3in. When harrowed this made a splendid job compared with the cultivator fallow. Mr. J. H. Nicholls believed in deep ploughing when the rainfall was good, but at present if this were practised the seed was buried too deeply. The depth of ploughing should depend entirely on circumstances. In his reply Mr. Sutton reminded members that he did not advocate cultivator fallow in seasons of good rainfall. Under present conditions cultivator fallow meant early feed and ensured clean fallow. No doubt the work done by a skim plough looked better at first, but after being worked again by the cultivator it would look much worse, as the rubbish ploughed in just below the surface would be brought up again. Replying to a question as to how he proposed to work the land the next time he cropped it, Mr. Sutton said he favored using a twin plough, ploughing a little deeper than the previous year.

## NORTHFIELD (Average annual rainfall, 19in.).

July 27th.—Present: 12 members.

**POULTRY ON THE FARM.**—Mr. J. Eisele read a paper on this subject. He advised the purchase of two distinct strains for breeding, the males of the one being mated to the hens of the other, and the progeny being kept separate. At the commencement about six breeding pens should be erected facing the north. A cheap roosting-house for the laying flock could be made 50ft. long, 12ft. wide, 6ft. high at back, and 7ft. 6in. at the front. A 6in. air space should be left between the back and the roof, and 3ft. sheets of plain galvanized iron should be placed sideways along the front. This structure would accommodate between 200 and 300 pullets. After chicks were 40 hours old they should have a mixture of 6lbs. cracked wheat, 3lbs. cracked peas,  $\frac{1}{2}$ lb. each of hemp, canary, and millet seed and 2ozs. linseed kept before them. Fresh milk should be provided for drink. After they were a month old a mash of scalded crushed oats, bran, and greenfeed, with pollard added to make a crumbly mass, should be given in the

mornings: to this 5 per cent. of the bulk of meat meal should be added twice or three times per week. Cracked grain should be available to them until they were four months of age. The birds selected for breeding should receive hulled oats; laying pullets should have mash consisting of chaffed greenfeed, two parts bran, three parts pollard, and ½ lbs. of meat meal twice or three times weekly to each 100 hens. The mid-day meal should consist of chaffed green feed, and for the evening wheat and oats and occasionally a few peas. Infertile eggs should be marketed; and he strongly advocated the system of selling by weight. An interesting discussion followed, and the writer was highly complimented on his paper.

August 4th.—Present: seven members and one visitor.

**HAYCUTTING.**—In dealing with this subject in a paper, the chairman (Mr. J. Dall) expressed the opinion that the greater part of the hay in this district was not a good marketable sample, as it was left standing too long. He advised cutting just after the bloom had fallen, and up to the time the grain was setting. The practice of making large, round stooks was not to be recommended, as the hay was likely to sweat, and therefore discolor. Long stooks to the width of four sheaves would be found more satisfactory. The hay should not be stooked until it had remained two days in the sheaves. Carting should be commenced a fortnight after stooking, but this should not be attempted if the weather were very hot. When commencing stacking a calculation should be made of the quantity of hay and the size of the stack based on this. A foundation of straw, wood, or any substance of similar nature that might be available should be used to prevent waste of the hay. In building, the centre should be kept well up, and this was best done by commencing in the middle and building out to the walls as each layer was put on. The width of the stack should be increased as it became higher, and before roofing was commenced the centre should be raised considerably. If the covering were of iron it would be found to last for a number of years and a good deal of trouble would be avoided. Square-ended stacks were more easily and cheaply covered. Every caution should be taken against fire, and a good plan was to plough a break of a few yards round each stack. In cutting chaff he made a practice of putting the butt end of the sheaf in first, and he claimed that this fed the machine more regularly than was the case when the heads were fed first. Mr. E. W. Kelley agreed that if the hay were cut in a greener state generally a better sample would be obtained. He preferred the round stook of from 50 to 60 sheaves which was more easily built and involved less waste than the long stook. Properly constructed sheds were the best means of protecting the hay from the weather. Messrs. Eastwood and Wright preferred long stooks, whilst Mr. Eisele advised building round stooks.

#### RIVERTON (Average annual rainfall, 20.48in.).

May 1st.—Present: 12 members and two visitors.

**THE HAY AND CHAFF ACT.**—Mr. H. H. Davie read a paper. He said:—“During the year 1910 an Act was passed to prevent the mixing of hay and straw, and the sale of same as hay chaff, and fixing the weight of a bag of chaff at 40lbs. The trade got over this Act, as far as the weight of the bag was concerned, by almost at once unanimously adopting 56lbs. as a bag. This was taken up by almost every merchant and dealer, and the 40lb. bag, which had been used in the Adelaide trade for 40 years, and which, as I will try to show, cost the consumers thousands of pounds, has gone for ever. Then the same complaint as had been made about the 40lb. bag arose with regard to the 56lb. bag, namely, that some of the cutters cut the price of chaff below value, and got their profits by selling 35lb. bag for 40lbs., and 50lbs. for 56lbs. Whether this is a fact or not, it is not for me to say; but if it is, the matter would soon right itself between buyer and seller. No sane man would buy a bag of chaff, even if it were a penny per bag less, if he found he was only getting 35lbs. or 40lbs., instead of 40lbs. or 56lbs., as the case may be. The same thing applies to mixed chaff. Surely no man would give, say, £3 per ton for chaff containing, say, two-parts hay and one-part straw, if he could get prime all-hay chaff for that price. If he could get the line for 10s. per ton under prime chaff, and it suited his purpose, why should an Act be passed preventing anyone producing a fodder which is highly valuable for feeding all store stock, and in times of drought in the past has been the

salvation of our States? So sweeping and strict is this Act, that not only has it altogether done away with a second quality of chaff, but prevented several merchants handling straw for the purpose of pressing, for horse bedding, packing, &c., as the Act will not allow anyone to have straw on premises or in a shed or building that is used for chaff. To deal in pressed straw now, one must have a separate plant and shed, representing a cost of at least £500, including press and engine to drive same. The result is that the Adelaide trade last year had to import about £3,000 worth of straw from Victoria. Before the Act was passed hundreds of tons of straw were cut with the binder, and stacked, with the hope of a market should the season be dry, and as soon as the season was assured it would be sold for pressing. As soon as this Act became law, no matter how scarce and dear hay might be, farmers, speculators, and dealers went right off it, and farmers burnt it or fed it in the paddock by running stock over it. Let me sound a note of warning here. Notwithstanding the Act, farmers should still cut stacks of straw, cover them well, and fence them in, for be well assured, by one who has had 50 years' experience in the fodder business, there will come a time again when they will be required, and they will return a good profit. Let chaff go up to £7 or £8 per ton, as it has before, and there will soon be a petition asking for the Act to be set aside, for a time, at anyrate. Now, to return to the standard bags. The 40lb. bag means 50 to the ton, 18 bags more than are necessary if 70lb. bags are used, and 24 if chaff were sold by the ton or cwt., as in all other States. Eighteen bags, at 5s. per dozen, is equal to an expenditure of 7s. 6d. per ton; 24 at the same price, 10s. per ton. Then it takes an extra man to handle the 56 bags. In fact, the extra handling all round should be put down at least 1s. 6d. per ton. Then there is the loss in weight. The Act is so stringent that we have to put into the bags 58½lbs., to allow for waste and shrinkage—that is, we lose 1lb. on every bag. This is not a big item to a consumer, using, say, a quarter of a ton a week, but a very big item to the hay merchant, who is putting out, as our firm are doing, 25 tons to 30 tons every day. It works out at a yearly value of £483 15s. There is also the cost of extra bags and handling, weighing, and storing, which can safely be put down at 1s. 6d. per ton. Now, I think enough has been said to prove that up to the present the Acts passed do not meet the requirements of the trade—to put it in a nutshell the present system increases the price to the consumer and gives the cutters and dealers a lot of trouble. Now, to get over the difficulty, I suggest an Act repealing the others, and setting out that all chaff be sold by weight at per ton of 2,240lbs., and at per cwt. or part of cwt. This would do away with the bag weight altogether. Instead of 40 bags for a ton, 26 bags would hold that quantity; that would save 14 bags, at about 6s. per ton. Every bag would be weighed out as the customer bought it; he would pay for the number of lbs. he got, or in case of ton or half-ton lots, it would be passed over a weighbridge, and the weigh bill obtained for it. All chaff should be sold 'bags as chaff,' or 'bags included.' They would then be the property of the buyer or consumer, and it would be to his interest to care for them, and not allow them to be destroyed, as is the case too often under the present system. The above is the system adopted in all the other States, and it works remarkably well; to my mind there could be nothing fairer for all concerned. When in Melbourne last year, I called on several of the large firms, and made inquiries as to how their system worked. They were all unanimous in the opinion that it was far before our system, and declared that a 56lb. bag would mean an extra cost to the consumer of at least 5s. per ton. One firm stated that it would increase the cost on their output for bags alone to at least a thousand a year." The Chief Inspector of Chaff (Mr. Geo. Quinn), to whom this paper was referred for comment, states:—"The writer of this paper doubtless is an experienced chaffdealer, but is hopelessly astray in his knowledge of the provisions of the legislation dealing with hay and chaff, and the conclusions he arrives at in relation to the operation of the same. For instance, there is nothing in the law to prevent any registered cutter cutting hay into chaff and straw into chaff on the same premises, and providing they are sold separately, any person wishing to obtain them may do so, and mix them in such proportions as he chooses, to feed to his store stock. The Act does not prevent any cutter of chaff keeping straw and hay on the same premises, or in the same sheds, so that this statement generally does not

apply, and has no connection whatever with the importation of £3,000 worth of straw from Victoria. In respect to the contention that the stringency of the Act compels the seller to lose 1lb. on each bag sold, owing to having to provide against shrinkage in weight, it may interest the writer to know that the weighing of hundreds of bags at chaffmills and stores, and the chemical analyses of samples taken, fail to bear out the statement excepting where water has been unduly added by the cutter. The statement that the loss of 1lb. from each bag 'is not a big item to the consumer,' when put in plain terms, means that if the consumer be robbed of 1lb. of chaff per bag, or 40lbs. in each ton, he will not notice it; but to the merchant with a big output, by an elaborate calculation, it may mean a loss of £1,133 15s. per annum. This sounds appalling, but those who are behind the scenes know it is a conflagration, which in many instances is averted—like others—by the timely use of a water hose. Regarding the details of the legislation the writer favors, he may be surprised to know he may now sell his chaff by the ton or portion thereof, even if it be only one-eightieth of a ton, say, a 28lb. bag—a lady's bag of chaff, as our Lyndoch friends desire to see legalised—and he may send it out in buckets, or barrels, or tubs, and the law will not interfere. Further, he may sell chaff in 70lb. bags, if he will take the trouble to mark them with a letter 'L,' as his guarantee they are not 56lb. or 65lb. bags. The contention that bags be sold as, or with, the chaff, seems to be generally favored by the trade, and doubtless will be given a trial in any future legislation, if the chaffcutters and dealers make their contention sufficiently convincing. As previously remarked, there is nothing in the present law to foster improvidence amongst farmers in respect to the matter of saving straw to supplement their hay supplies in seasons of scarcity of fodder; but the law does prohibit headed straw, binder twine, cockspurs, poppies, and such like being cut up and mixed with clean hay, and sold to consumers at full market rates. It also prohibits the addition of foreign matter, such as mice, and should be amended in such a way as to render any chaffcutter liable to severe punishment who sends out chaff which naturally should contain 6lbs. of water (moisture) in each 56lb. bag—with 9lbs. in each standard bag of that capacity."—Ed.]

**RUSTY HAY FOR CHAFF.**—When cutting rust-affected hay for chaff members advised cutting it dry, instead of following the usual practice of damping. A considerable quantity of the rust would then blow away.

**RIVERTON** (Average annual rainfall, 20.48in.).

July 13th.—Present: 14 members and five visitors.

**PRODUCING A CLEAN WHEAT SAMPLE.**—Mr. J. Phillips read a paper. He said—"One of the first points a farmer must aim at is to get the land on which he intends to grow a wheat crop clean. He should look to the seed intended for sowing; this is even more important than the land question. Care should be taken that there is no smut, barley, wild oats, charlock, wild cabbage, or white heads in it. The lastnamed interferes with the even running of the seed through the drill. One should avoid having grains of different varieties mixed, because this may prevent the farmer selling the crop as being true to kind for seed purposes. The next question is harvesting. There are various methods—combined harvester, stripper, and thrasher. Of the three I prefer the combined harvester. To work this machine satisfactorily the operator must be experienced. He must not lose sight of the necessity for producing clean wheat. When starting a harvester care should be used in noting the size of the grain. It does not follow that because the machine made a good sample while reaping one kind of wheat that it is set right to reap another variety, although growing in the same paddock. Let us compare the two wheats, King's Early and Federation, grown under the same conditions. The first is a long, large, bold grain, while the latter is small, plump, and shotty. Although we may be able to reap both without altering the set of the machine, we are not treating one of them fairly. If the beaters are not set at a proper distance from the diamonds, the result cannot be good; if too far away the wheat is not thrashed when first entering the machine; if too close the grain is liable to be cracked. There is just a happy medium which can only be obtained by a few trial runs. A good plan is to take a stalk of the crop and adjust the beaters so that they clear the diamonds when the node of the straw is placed between them.

This node will vary in size in different varieties. After examining the damp weather, which cannot be altered much except as far as speed is concerned, we come to the sieves or screens. These need a good deal of attention to secure good results. As the wheat leaves the damp weather it comes on to a large screen, with holes about 1 in. x 3 in. This first screen allows the wheat to pass through, but retains the unthrashed heads that may have got past the beaters in damp-weather. They are eventually taken back to be thrashed again. The wheat which falls through, comes on to another screen, which, if not properly adjusted, will spoil the sample. To keep out white heads this second screen should be open just wide enough to allow the particular variety of wheat to easily pass through and no more. At the same time it should be capable of stopping any white heads, which are gradually taken back to the thrasher again. Next we come to the revolving screen, through which the wheat passed just before entering the grain box. Its work is to remove the broken and cracked grain, also wild cabbage and wild oats. The only way to make it do this work satisfactorily is to keep it clean. A good plan is to fasten some sheepskin to a small piece of wood, running the whole length of the screen, attaching this inside of the lid of the iron covering which encases the revolving screen, applying just enough weight to cause the wool to brush against the screen as it revolves, and thus prevent the small grain, &c., blocking the openings. When working the ordinary stripper, care should be used in setting the beaters, otherwise unthrashed heads, or cracked grains will be the result. In the first case there will be a lot of trouble where the ordinary winnower is used in cleaning. The question will arise why should a farmer go to all this trouble adjusting his machine during a busy time, when the first setting will do to get the whole crop off. Under present conditions I say do not do it. I don't intend to say anything about the farmer who is making a special point of producing seed wheat; but to the wheatgrower what inducement is there for him to clean his grain when he can get just as good a price for his wheat with the screenings in. The question of retaining the standard of South Australian wheat in the old world, rests two-thirds with the merchant and one-third with the farmers. Let the merchants educate their agents to buy well up to a clean sample. Anything not coming to that standard of cleanness should be paid for at a lower rate, even if from an old customer. I know it will cause a lot of bad feeling the first year, but inside of two years the trouble will have passed. If the merchant cares to pay the good farmer for his trouble of making a good sample it will not be long before the State regains its reputation of producing the best wheat in the world. The State itself and the farmer will benefit by getting better bran and pollard, and the miller by not having to expend money on extra cleaning machinery." In discussing the subject Mr. R. H. Cooper mentioned that in earlier times it was the practice in South Australia to put the grain through the winnower two or three times, in order to thoroughly clean it. The Hon. W. Hannafor, M.L.C., expressed the opinion that with the present day machinery the flour millers could more cheaply and more effectively clean the grain than the farmer. Mr. H. A. Davis emphasized the necessity for carefully adjusting the harvester and keeping the sieves clean. Mr. W. B. Davis thought it important to thoroughly clean out the harvester of one variety before it was put into another crop.

SALISBURY (Average annual rainfall, 18.57 in.).

August 4th.—Present: 11 members and two visitors.

QUESTION BOX.—A number of questions were dealt with. It was thought that the best crop for summer feed in a dry season was sorghum, which, with a fair rain, should yield a profitable return. Millet should be tried, but it was unwise to crop land with wheat the year following the summer crop. In considering whether it was advisable to crop every third year and keep more stock, it was stated that the yield would no doubt be greater, and if the land left out were sown for feed the practice suggested would no doubt be payable. Oats, it was said did well for feed in this district. Fowls that showed a tendency to eat their eggs should be destroyed. Charcoal was a good preventive for diarrhoea. Hens that were kept in a too fat condition would not lay well. It was thought advisable in working red ground to cultivate to a greater depth than that to which the wheat was sown, but when black or sandy soil was being worked it need not be cultivated to a greater depth than it was seeded.

## TWO WELLS (Average annual rainfall, 16.36in.)

August 4th.—Present: 15 members and one visitor.

**DAIRYING.**—Mr. P. C. Cooper contributed a paper. Suitable country for dairying he said, should be capable of growing an abundance of maize, sorghum, &c., or where irrigation could be carried on, lucerne, to ensure a supply of green feed all the year round. This was essential to heavy milking and to keep the cows in good health. An ideal spot for growing maize and sorghum was where there was an overflow from a creek or river each year. This was much better than irrigation by means of either engines or windmill. In selecting cows there were several points to be considered—different localities suited different breeds. A good cow should have plenty of udder room. A nice square udder, with large milk veins; thin neck and tail, and be straight along the back, wide between the eyes, and of good temper. Her milk should test over 4 per cent. of butter fat on an average milking and measure over 3gals. per day for butter-making. If milk were the objective, the deepest milkers, so long as they yielded milk testing over 3.2 per cent. were recommended. He favored the Holstein-Jersey cross—the Holstein being a heavy milker and the Jersey yielding milk very rich in butter fat. Another good cross was the Shorthorn-Ayrshire. These calves were better for fattening for market than the Holstein-Jersey cross. Bulls for stud purposes should be pure bred and from a heavy milking strain on both sides. The farmer should rear his own heifers. By so doing he was able to sell some of the older cows each year and still keep up the herd by selecting the best. He thought the Babcock milk tester was the surest way to ascertain the quality of the milk yield. *The Cow Shed.*—This should be paved with bricks and then given a thin wash of cement. It should have a drain at the rear of the bail and a cemented pit at the end of the shed for all refuse. The shed must be hosed out daily, and have a slight sprinkling of lime dusted over to ensure cleanliness. Milk would more quickly absorb an odour than any other liquid. At milking time the cows should be quietly handled. An excited cow would not give her milk freely. Fast milkers were preferable; care should be taken to strip the cows properly, as the last of the milk contained most of the cream. *Separating.*—The milk should be kept as nearly as possible at the same temperature as when taken from the cow until it was separated, then the cream should be cooled off. On no account should it be mixed with the staler cream while warm. The mixing should be done thoroughly. For churning the cream should be ripe and not above a temperature of 62°. When it began to break into lumps about the size of large shot the buttermilk should be drawn off and brine put in the churn, which should then be turned for another five minutes. The butter would then be ready to be put through the worker. The salt should be sifted and mixed as the butter was being worked and washed, 4oz. of salt being allowed for every pound of butter. The separator and dairy utensils should be scalded immediately after use; a little soda also being used. The separator room and dairy should have cement floors. *Separator Milk.*—Separator milk when cool, and with a small quantity of pollard mixed, constituted an excellent pig food. Calves, if fed on this would fatten much more quickly, and did not scour as they did on separator milk alone. Before feeding the froth should be skimmed off the top of the milk. It was always wise to have a milk fever outfit available, as when the grass was at its best heavy milkers coming in at that time were liable to develop milk fever about two or three days after calving. He had known a cow to be affected three months after calving. In cases of dry bibles the following simple remedy had been found effective:—Make up a drench of 32ozs. Epsom salts, about 1 pint treacle, and 1 pint of ordinary ale. Give it as soon as the animal showed symptoms; smear its nose twice a day for a week or more with Stockholm tar, and feed well on sloppy bran. In drying off cows great care should be exercised. The best way was to put the animals off once a day, then once every other day, and so on until the milk had completely gone. They should be allowed to have a rest before coming in again, and should be out at least six weeks or two months, they would then come on with renewed vigor. In discussing the paper Mr. Dawkins said it was not profitable to rear heifer calves, as a good cow could be purchased for about £4. He advocated feeding the cows while they were being milked, but other members thought it best to feed afterwards. In answer to a question, the writer of the paper said that in drying off cows which were being milked every other day, the milk should not be used. Mr. Hart contended that lucerne without chaff was of little value, and he would give one feed of lucerne and two feeds of chaff per day. Bulls should be yarded, and the cows put with them as the owners desired. It was mentioned that a farmer was milking two pairs of twin cows and all four were good milkers. Members generally agreed that few districts were better suited for successful dairying than Port Gawler.

**LYNDOCH, July 2nd.**—**IMPROVING THE INTEREST OF YOUNG MEMBERS.**—An interesting and instructive paper of considerable length was read by Mr. P. N. Burge. He dealt with the advantage that accrued from membership of the Agricultural Bureau, and emphasised the need of regular and punctual attendance at meetings. He mentioned several means of encouraging young men to take an active part in the meetings, in particular question boxes, short discussions, &c. He expressed the view that it was wise to have a paper read at every meeting of the Branch.

**LYNDOCH, August 6th.**—A paper dealing with co-operation amongst agriculturists was read by Mr. H. Kennedy.

**STOCKPORT, August 6th.**—**CO-OPERATION AMONGST FARMERS.**—Mr. Nairn contributed a paper on this subject.

## YORKE PENINSULA DISTRICT. (TO BUTE.)

**DOWLINGVILLE** (Average annual rainfall, 13in. to 14in.).

July 31st.—Present: six members.

**POULTRY.**—A paper on this subject was read by Mr. Phelps. He advised the provision of a galvanized iron shed within a yard enclosed with 6ft. wire netting for the poultry. The birds could be allowed their freedom during the day, but they should be fed and locked in at night. Pure-bred birds paid best, and the best laying strains only should be bred from. Chicks should be yarded apart from the adult fowls. Eggs that were over seven days old should not be set, and the incubator was the most satisfactory means of hatching. Only infertile eggs should be marketed.

**KADINA** (Average annual rainfall, 15.88in.).

August 1st.—Present: 10 members and one visitor.

**MIXED FARMING.**—In a paper on this subject Mr. E. H. White expressed the opinion that it was unwise to depend solely on wheat to provide the income on the farm. He thought it advisable to sow oats for hay and feed on stubble land, and devote the fallow to wheat-growing. As many sheep as possible should be carried, due regard being paid to the disastrous effects of over-stocking. Foals should be bred to replace old horses in the team, any surplus being disposed of. Continuing, the paper read:—"It is a great mistake to breed too many light sorts. When a shortage of grass occurs 25 or 30 useless animals soon dispose of a big haystack. It is wise to keep a few pigs, to be turned into bacon and ham for winter requirements. A farm should have at least 300 laying hens. Monkeys eat more and produce less than well-bred birds, and with the waste land around most homesteads utilised as pens, even more than the number stated could be kept. Access to the horseyard by the fowls prevents the flies becoming a pest, and to the hayyards means the picking up of a good deal of grain that would otherwise be wasted. Haystacks and barns should be made mouseproof, as the damage done by mice in an average year would pay the cost of mouse-proofing a 70-ton stack, while the damage to bags, wheat, and other foodstuffs wasted would easily pay the small outlay. A blacksmith's and carpenter's shop with a few pounds worth of tools saves time and expense. Many breakages could be repaired a dozen times while the farmer was travelling to the nearest smithy. A few harness-mending needles are of great assistance. A collar lined on the farm and made to fit the horse, with the hair where it is needed, is the best preventive against sore shoulders. A little time on wet days spent in digging in a garden is well spent." Most members were of the opinion that mixed farming was desirable.

**MAITLAND** (Average annual rainfall, 20.08in.).

August 1st.—Present: 12 members.

**ROBBERS AND WASTERS ON THE FARM.**—A paper under this title was read by Mr. G. P. Gapp. He said:—"The most prevalent of these is poultry not properly attended to. No one doubts that to a wheatgrower carefully kept poultry constitutes a very profitable side-line, but fowls allowed the freedom of the farm will feed and nest in the stockyard or in the horses' mangers. I have often wondered whether the advantage of keeping fowls is not considerably counter-balanced by the loss sustained in the feed value of the hay. On the other hand, I have read that horses in stables in which fowls are run experience considerably

less trouble with the bot fly. Different methods of dealing with mice have been devised, but unfortunately in most cases little attention is given this destructive pest. With regard to crop robbers, one has only to pick up a stump or stone shortly after seeding to find a quantity of young plants which have been checked by its presence. Every weed left in a cropped paddock and every tree in the close vicinity of a crop is robbing the soil of moisture. In certain districts locusts, kangaroos, rabbits, &c., have to be coped with. Climatic conditions which encourage the development of blight, rust, and smut in the crop, and the hot winds that play havoc with the crops must be considered. Takcall, salt patches, and claypans all have their disastrous effect on cereals.

## WESTERN DISTRICT.

**BUTLER** (Average annual rainfall, 16.6lin.)

August 3rd.—Present: 13 members and one visitor.

**FALLOWING.**—Mr. R. W. Phillis read a paper on this subject as follows:—"Fallowing should be commenced as soon after seeding as possible. Early fallowing conserves the moisture in the soil better than late fallowing, and farmers should finish in time to get the loose stumps and stones off the ground so that they can work it back. I consider 200 acres of well-worked fallow better than 400 acres ploughed roughly and so left until the next seeding. The six-furrow share plough is the best implement to use, as it pulls up more stumps than does the disc plough. The latter plough should be used for working back the land; 3in. to 4in. is quite deep enough to plough for this district. Harrowing should be done after each rain. It would pay farmers in this district to summer fallow, say, about 50 acres as an experiment; just ploughing after harvest and leaving the land until after seeding, then fallow again. The first ploughing would let in the winter rains and leave the soil in good working condition." Members generally agreed. Mr. Jas. Charlton also contributed a paper on this subject. The best time to fallow, he said, was just after seeding. In scrub land the ground should be ploughed to a fair depth wherever there was broom or bushes, and it should be cross-harrowed to pull out the roots. One hundred acres of good fallow was better than 300 acres of scratched land, as one should not grow bushes and wheat together. Members entirely supported the remarks of the paper writer.

## CARROW.

July 30th.—Present: six members and one visitor.

**BULK HANDLING OF WHEAT.**—This subject was introduced by the chairman (Mr. Cawley) who expressed the opinion that no advantage would result from the introduction of the proposed system, with which members generally agreed.

**FARMERS' CLUB.**—The establishment of a farmers' club in Adelaide was discussed, and the opinion was expressed that considerable good would follow such a movement.

**SCORCHING MALLEE SHOOT.**—The matter of an effective machine for the destruction of mallee shoots was discussed, and on the motion of Mr. C. Storrie, seconded by Mr. F. J. Anear, it was decided to request the Advisory Board to recommend the Government to offer a substantial bonus for the invention of a satisfactory shoot-scorcher.

**COLTON** (Average annual rainfall, 17.0lin.)

August 1st.—Present: nine members and four visitors.

**STOCK-WATERING FACILITIES.**—Mr. M. D. Kenney read a paper on this subject. In the course of his remarks he said that this was a most vital question in Eyre's Peninsula. Where it was impossible to get water by sinking wells the selectors had to put down underground tanks for their stock water. A fair-sized farm required not less than 300,000galls. of water, which would need from 10 to 20 tanks. The cost of putting down these tanks would not be less than £600. In places where good natural runs were not obtainable these would have to be made with cement and concrete. At Smoky Bay he saw a large tank of water built in between two sandhills. By cutting and burning the trees which grew on the slopes of these hills an oily surface was obtained. This had given a good water run for three years, and by that time stock had made several tracks to the tank, and eventually a good permanent run was obtained. The hundred of Colton was

a well-watered district, but settlers did not seem to realise what advantage and comfort it would be if the water was laid on to the house, stable, paddocks, &c. The cost of this (with a 1½ in. service) would be £87 16s. 3d. per mile, and a mill with piping for a well 100ft. deep would cost an additional £33 8s. He cited a case in which a man had rented a Government plant, which with freight cost him under £5; he and two men sank to a depth of 120ft. in 14 days, with very good results. Another farmer carried his water in pipes for two miles. A convenient method for those who depended on tanks was to erect a windmill on wheels, with a tank and trough, and as one tank was emptied move the structure to the next, and so on. He had seen one of these, which had proved to be very cheap and handy to work.

#### ELBOW HILL (Average annual rainfall, 11in. to 12in.)

August 1st.—Present: 14 members and four visitors.

**CULTIVATION OF THE LAND.**—A discussion on this subject was initiated by Mr. J. Jacobs. Previous to sowing, he said, to secure best results in those years of poor rainfall, it would be a good plan to work the land lightly after rain so that when following one would be able to extend the ploughing over a longer period. The soil would retain moisture longer if only harrowed after rain before ploughing. It was a mistake to plough in the stubble when following, as there was not sufficient moisture to ensure the decay of same; thus the land would become consolidated. The stubble should be burnt. Mr. Chilman did not think harrowing previous to following beneficial. He favored burning the stubble. Another member agreed with Mr. Jacobs, and was of the opinion that more time should be spent in preparing the soil in this neighborhood than was generally the case. He advocated ploughing under greenstuff where practicable. The Chairman (Mr. W. T. Cooper) favored sowing oats after wheat crops. He thought that deep sowing was conducive to the development of takeall. Mr. P. Wake had experienced no difficulty with takeall in fallow as a result of ploughing in stubble. The Hon. Secretary (Mr. G. F. Wake) favored following deeply, with frequent light workings afterwards. A visitor mentioned that ploughing under straw when following was not harmful, but he would on no account plough it under when the land was to be sown the same season. He had seen a very good crop of oats following a crop of wheat which had been badly affected with takeall.

#### GOODE (Average annual rainfall, 12in. to 13in.)

July 8th.—Present: 12 members and four visitors.

**SHEEP ON THE FARM.**—Mr. L. Wile contributed a paper on this subject. Sheep, he said, could be kept very profitably in this district if given proper attention. He recommended placing them on the fallow once or twice a week as soon as the weeds began to show, but not immediately after a heavy rain, which might cause the ground to puddle. It was a mistake to over-stock, 12 sheep to 100 acres was sufficient. They should be changed frequently from one paddock to another, and always have access to water. He deprecated the practice of running horses, cattle, and sheep all in the one paddock. He considered that each sheep should return about 5s. worth of wool per year. In discussing the paper, Mr. L. B. Hughes advised keeping not less than 200 sheep. Mr. W. Packer agreed with the writer in his remark that sheep were the best means of working fallow and keeping it clean. Mr. Morcombe emphasised the value of sheep for keeping weeds in check, and Mr. W. Tainsh advised farmers to fence off two parts of their cleared land for them, and have alternate runs. Members generally agreed that these animals would be found very profitable to the farmer.

#### GREEN PATCH (Average annual rainfall, 26.56in.)

August 3rd.—Present: six members.

In connection with the visit of Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S., to Eyre's Peninsula, the following questions were asked:—(1) Instead of using ground limestone for sweetening the soil, would not gypsum, which in some parts of the district is plentiful, answer as well? (2) On account of the heavy rainfall of this district, would not some of the water-soluble super. wash out of reach of the plant. Mr. Colebatch replied as follows:—(1) No, not at all. Gypsum is a neutral salt, and therefore will be of no value for the purpose of making "sour" soil "sweet." Lime, on the other hand, is an alkaline compound, and therefore acts as a corrective to soil acidity. (2) Generally speaking, the residues from heavy applications of superphosphates will not leach out of the land. In very light open lands, a certain amount may be washed down into the lower layers. On ordinary clays, clay loams, loams, or sandy loams, however, the phosphatic residues

are retained in the surface soil. Investigations conducted by Dr. Dyer in connection with the Rothamsted fields have shown that practically every pound of phosphoric acid added to the land for 50 years can be accounted for in the produce grown, and the increased amount of phosphoric acid in the surface soil at the conclusion of the half-century.

#### MILTALIE (Average annual rainfall, 14.55in.).

August 1st.—Present: 12 members and four visitors.

**Pigs.**—In a short paper on this subject Mr. J. L. Jacobs advised farmers to keep four to six pigs on the farm to provide a supply of pork and bacon. He mentioned that he had purchased three eight-weeks old pigs at 8s. each. These were fed on milk and kitchen slops for six months, then for three months on oats. The first killed weighed 290lbs., and in addition to providing meat for three weeks, two rolls bacon sold returned £4 0s. 10d.; the two hams, which weighed 52lbs., realised £2 12s., a total return of £6 12s. 10d. The cost of oats, namely four bags at 6s., £1 4s., deducted from this left a net return of £5 8s. 10d. Mr. L. J. P. McEachen said that where farmers raised pigs it was advisable for them to grow barley for fattening. Mr. P. G. Wilson advised disposing of these animals as woiners. Mr. J. P. Story preferred the Berkshire, and members generally agreed that this class of stock provided a remunerative investment to the farm.

#### MITCHELL.

August 1st.—Present: 17 members and two visitors.

**FALLOWING.**—A short paper on this subject was read by Mr. D. Sampson. He preferred to use the mould-board plough, and would commence work not later than July, using two horses to each furrow. The deeper the land was worked the better, and it should be harrowed immediately after ploughing, and worked again with a good cultivator in September or October. A further harrowing should follow in the event of a good fall of rain. The crop should then be put in after a late cultivation. Members generally agreed with the paper.

#### ROBERTS AND VERRAN.

August 11th.—Present: 11 members and one visitor.

**CARE OF THE WORKING HORSE.**—Mr. D. Hoare contributed a paper on this subject. He thought horses should be provided with suitable accommodation. Eight hours regular work per day was quite sufficient. Spells of at least a fortnight should be given after seeding and harvest, and careful attention should be paid to the feeding. Where hay or hay chaff was available, providing the feeding was regular and judicious, there should be no trouble; but this was not the case where cocky chaff was used extensively. He advised mixing boiled oats or boiled wheat with the cocky chaff, which should previously have been sifted in order to remove sand, &c. He would not allow the animals to drink before they started work, but would water them before feeding. Rock salt should be kept in the mangers, and every care should be taken of the animals' shoulders, which should be brushed every morning before work was commenced. Collars should be oiled, stuffed, and lined annually. The same harness should always be used on the horses, and it should be carefully buckled. Mares in foal should be very carefully handled, and should not be put to work for a month or six weeks after foaling. An interesting discussion followed, in which Messrs. F. Masters, W. Kunst, and W. McCallum took part. Mr. G. Plew thought dry wheat preferable to boiled wheat for feeding horses, with which Mr. Kunst agreed. Members differed in opinions in regard to this matter, and Mr. McCallum expressed the view that feeding dry wheat was likely to increase trouble with sore shoulders.

#### SALT CREEK.

August 1st.—Present: 14 members.

**FALLOWING.**—The Hon. Secretary (Mr. H. F. J. Hill) read a paper as follows:—"It has been proved that fallowing is one of the most important factors in successful agriculture. This should be commenced as soon after seeding as possible. If the soil is dry and too hard to be ploughed to the depth required, it is a good plan to go over it with a cultivator or light plough, cutting all grass and weeds and burying seed that may be left uncovered. By so doing the land is got into better order for the plough after sufficient rain has fallen to enable it to be fallowed; it will not become hard so quickly, and will

enable the farmer to keep on ploughing. The depth of ploughing is generally determined by the nature of the soil. I have a firm belief in deep ploughing in land likely to drift, to turn the heavier soil to the top and the light, dry soil right under. After the ploughing has been completed the following methods of cultivation should be adopted:—Harrow as soon as possible and after spring rains; when the weeds begin to show up put the cultivator over the fallow, to kill all weeds, and leave the land in a fit state to withstand the summer winds. If the soil is not too rough scarifier harrows after harvest will improve it. The land should receive shallow working up to the time of sowing to ensure a perfect seed bed." The majority of members agreed with the remarks contained in the paper. Others preferred a skim plough to the cultivator for working over the fallow; it would destroy more of the weeds.

#### YABMANA (Average annual rainfall, 15·14in.)

August 1st.—Present: nine members and four visitors.

**THE HOMESTEAD AND ITS OUTBUILDINGS.**—The Hon. Secretary (Mr. H. P. McCallum) read a paper on this subject. The dwelling-house should be as near the centre of the farm as was conveniently possible, he said. A small fruit and vegetable garden and a few vines should be planted, a small well-attended garden being a greater asset than a large one not given proper attention. The vegetable and flower plots should be protected by a breakwind. The outbuildings should be distant about 200yds. to 250yds. at the back or side of the home. Wood and iron stables and sheds were certainly preferable, but for the beginner the cheaper structure of timber with a straw roof would be found very serviceable. The stable should face the east to protect the horses from the cold westerly winds. If allowed plenty of yard room they did better than when tied up over night. A loosebox should always be provided for weaning foals or forsick horses. It was best to build the chaffhouse of wood and iron with a jarrah floor. The machine shed should face the east and have the ends and the back enclosed. Cow sheds were needed, as milking in the open was bad for the cows, and they would not give the same quantity of milk as when milked in a warm shed. A few gums, he said, added to the beauty of the place. In discussing the paper Mr. J. F. Robertson said he would plant about 50 to 60 vines and 40 fruit trees. He advocated tying up the horses in the stable over night, for if let loose there was a danger of their being kicked. Mr. F. Schuman favored a stable with a straw roof, it being cooler in summer and warmer in winter. He would tie up the horses at night to ensure each animal getting its full amount of food. The idea of a fruit and vegetable garden was a good one. The Chairman (Mr. F. A. Beinke) said a farmer could manage a fair-sized garden in conjunction with his farm. He would have the horses loose in the yard. This enabled them to roll and dry instead of necessitating their remaining in a sweaty condition over night.

#### YADNARIE (Average annual rainfall, 14·09in.)

July 31st.—Present: 17 members and 55 visitors.

**ENGINES ON THE FARM.**—Papers dealing with this subject were read by Messrs. C. E. Stubing and R. H. E. Parbs. Mr. Parbs said petrol was certainly a little more expensive, but being a higher inflammable, and therefore a quicker explosive fuel than kerosine, it did at least 35 per cent. more work per gallon than kerosine; this made up for the extra cost. If a six horsepower oil engine were turned into a petrol engine by supplanting the vaporiser and hot tube with a carburettor and a high tension magneto and plug it would give off about eight horsepower running in petrol. This was the reason that an oil engine was more massively built, and why it could be run at a lower rate of speed. It required a larger volume of cylinder space, and to have this the whole engine needed to be made heavier. He did not think there was much danger of fire with the petrol engine, and there was less trouble in starting than with the oil engine. A lengthy discussion followed, members being divided in opinion as to the relative advantages of the two different types of engines. A vote on the subject revealed that 15 favored the petrol and 17 the oil engine.

**PENONG, July 11th.**—A paper dealing with what was characterised as a new fodder bean was read by Mr. W. Saunders. Information relating to the growth and value of this plant was given.

**YALLUNDA, August 1st.**—**CO-OPERATION AMONGST FARMERS.**—A paper on this subject was read by the Chairman (Mr. F. Olsten), and an interesting discussion followed. [This subject will be dealt with at the Congress of the Agricultural Bureau in September. The report of this gathering should be read for any further information desired.—Ed.]

## EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

## BERRI.

August 1st.—Present: 23 members.

**AFFORESTATION.**—In initiating a discussion on this subject, Mr. Stachling emphasized the necessity for carefully guarding our forest lands and preventing destruction of young timber. Stock and sheep in particular should be kept off the swamp country to give the saplings an opportunity to become established. Messrs. Arndt, Lewis, Mills, and Norman also spoke, and it was decided to take steps to inaugurate a branch of the Forest League in this district.

**PRUNING DEMONSTRATION.**—It was reported that an interesting and instructive demonstration of pruning was given by the Horticultural Instructor (Mr. George Quinn), at the Berri Irrigation Farm, on July 8th. In the evening following, this officer gave an address on the planting and growing of young trees to an appreciative audience.

## BORRIKA.

August 4th.—Present: 22 members and six visitors.

**BREAKING HORSES.**—Mr. G. Stephen contributed a short paper. He did not think it wise to break horses to harness before they were 3½ years old, and even then they should be given little work until 4 years of age. In the case of saddle horses, the breaking could be done when the animals were 18 months old, provided they were not made to carry a heavy weight. At 3 years of age they should be quite capable of doing any reasonable work required of them. In discussing the paper, several members mentioned that they had broken in horses earlier than recommended by Mr. Stephen without any ill effects. Messrs. Weber and Wilhelm advised training horses to the use of the open bridle.

**HANDLING WHEAT.**—Mr. V. V. Brown read a paper on this subject. He strongly advised the inspection and overhauling of all harvesting machinery, &c., before harvesting was commenced. Sites for the wheat heaps should be selected, and all other preparations completed. Until the farms in the district were free from stumps it would be found best to use the stripper and motor winnower in harvesting the crop, that was, provided the cost of labor did not become too expensive, in which case the use of the harvester or reaper thrasher might be found more profitable. For carting wheat a wagon with 6in. tyres, capable of carrying 70 bags or more, would be found best. He thought farmers in this State would gain nothing by the introduction of the elevator system of handling wheat. The relative advantages of the harvester and stripper as a means of gathering the grain were discussed by members, and instances given of the satisfactory use of both machines. Mr. Seary advised providing a layer of cocky chaff on the site of the wheat heaps to prevent grain being lost in the sand.

## COOMANDOOK (Average annual rainfall, 18.01in.).

August 1st.—Present: 15 members and eight visitors.

**FENCING.**—A paper dealing with this subject was read by Mr. E. H. Luxmoore. He said:—“A good fence is always a valuable improvement to a property, and the Government would be well advised if they advanced material and insisted upon boundary fences being erected within two years on all new country taken up for farming. Fencing is a work which, to a certain extent, can be done by degrees, and added to afterwards without greatly increasing the cost. A fence to keep in horses and cattle is required first, and later sheep; and there is no doubt that eventually fences will be required to keep out the rabbits. We have in this neighborhood a few examples of good and serviceable fences, but there will always be a diversity of opinion as to which is the cheapest and most efficient. Personally, I am in favor of a boundary fence somewhat on these lines:—A stiff wood-and-iron post every chain, with five or six light angle iron posts between. A 12-gauge barbed wire on top, and two No. 8 plain iron wires. The bottom wire 18in. from the ground, and the middle 3ft.—height of fence, 3ft. 8in.—This fence would hold great stock, and when a sheepproof fence is required, it would take 42in. netting, which is allowing 6in. for bending over at the bottom. The netting would, I think, be the cheapest in the long run, and the Government will advance it through the district councils on very easy terms. Straining posts should not be more than 10 chains apart, and less where the ground is undulating, as the iron

posts will be drawn if the strain is across a hollow. Where there is scrub, and a likelihood of fire, it is advisable to use all iron posts. I have erected some fencing with the stiff post and strainers made of two T iron posts, 1½ in. x 1½ in. x 1½ in., put back to back, and driven into a block of wood, which is put into the ground to the required depth. I used sleeper ends for the blocks. Angle-iron struts can be used for the corner posts. This is a cheap post, can be easily carted and handled, will stand a good strain, and is fire-proof. A good plan where wooden posts are used, and there is a danger of fire, is to run the plain wires on the outside edges of the posts, instead of through a hole bored in the post. They can be secured in position by means of tying wire run through a hole bored about 2 in. from the edge of the post. This is also an advantage if netting is used, as it enables it to be strained much tighter. Another advantage is that if a post is burnt or injured, it can be replaced without interfering with other portions of the fence." In the discussion that followed Mr. C. Wilkin said that he considered the "T" iron preferable to "angle" iron posts. On account of the undulating country in this district, he thought it unwise to use all iron posts, and even where there was a danger of fire it would be advisable to use one wood to every four or five iron posts, and clear the scrub near the fence. Most members agreed. On the motion of Mr. M. Wilkin, seconded by Mr. C. Hillman, it was decided to write the Advisory Board, asking them to recommend the Government to provide fencing material for boundary fences, on same condition as wire-netting was provided by district council, to settlers on newly opened country.

#### COONALPYN (Average annual rainfall, 17·49 in.)

August 7th.—Present: seven members and one visitor.

FENCING.—In a paper on this subject Mr. J. F. Pitman advised the selection of well-matured trees for posts. The bark should be removed from these. For preference he would have a fence 3 ft. 10 in. high, the posts being set 20 in. in the ground. The strainers should be from 2 ft. 6 in. to 3 ft. in the ground and 4 in. higher than the smaller posts. One wooden post with two T-iron standards should be used for every 30 ft. For great stock two barbed and one plain wire would be found sufficient; but for sheep, and keeping out rabbits, 3 ft. 6 in. x 1½ in. mesh netting was advised. This should be let 4 in. into the ground. He recommended placing a stone at the foot of the struts, cutting away the sharp edge of the wire holes in the strainers, using not less than four ties between each panel for the netting, dipping the end of the netting to be placed in the ground in oil of tar, placing stones along the fence line, which afforded an excellent firebreak.

#### CRESSY.

August 1st.—Present: 14 members and one visitor.

The inaugural meeting of this branch was held at the homestead of Mr. Angus, and an address was delivered by Mr. H. J. Finnis, of the Department of Agriculture.

Mr. Mann reported that he had sown plots of Gluyas, Cumberland, Yandilla King, and Zealand Blue wheats under identical conditions. Up to date the Cumberland was showing to best advantage. In the case of two plots, one of which was sown without and one with super, a very marked difference was observed in favor of the latter.

#### GERANIUM (Average annual rainfall, 16 in. to 17 in.)

August 1st.—Present: 19 members and four visitors.

MIXED FARMING.—The Hon. Secretary (Mr. W. J. Morcom) read a paper on the above subject. He contended that mixed farming should be given more attention than it had received in the past, especially in face of the dry seasons through which this State was now passing. One could not, he said, expect to get a very large income from wheat-growing alone. He cited several side lines which were a source of income. A few good cows would return a good profit. Some pigs, which could be practically solely fed on milk and spare grain, screenings, &c., would also prove profitable. It would be advisable to keep two or three breeding sows, each of which would rear at least two litters a year, which could be disposed of at an average of from 10s. to 12s. per head when six weeks old. Pigs, well fattened, at six months would sell at about £3 or £3 10s. each as baconers. Sheep should certainly be kept on every farm. In areas where fences were not sheep-

proof he would advise farmers to fence off a small place sufficient to grow sheep enough for their own requirements, which, he felt sure, would be more profitable than buying meat. He mentioned poultry as a sure source of a small daily income if properly looked after. A farmer should rear early chicks, thus getting pullets that would lay during the winter months—the cockerels could be fattened and marketed.

#### KINGSTON-ON-MURRAY.

August 7th.—Present: 10 members and four visitors.

**PLANNING AND PLANTING IRRIGABLE LANDS.**—The hon. secretary (Mr. E. W. Chaston) gave an address on this subject. An ideal block, he said, was one that could be watered without scouring, and yet not so slowly that the trees nearest the channel would have too much water before those at the opposite end of the row became properly watered. Each tree and vine should be so planted that it could be cultivated with a two-horse implement. In this district from 3ft. to 1ft. (according to the looseness of the soil) per chain, proved sufficient fall, keeping in mind the looser the soil the greater the fall. The speaker condemned the practice of planting trees and vines too closely together. If 80 trees per acre could be made to produce as much fruit as 100 on the same area, he would advise the planting of the lesser number, as the cost of planting, cultivating, and watering would be lessened. Plenty of room for turning on the headlands should be allowed, say 20ft. The supply tank, if underground, where possible, should be made about 20ft. higher than the land on which the house and sheds were erected, so that water could be supplied by gravitation for domestic supply. It was suggested that apricots, prunes, and apples would do best on the heavier soils, and peaches and oranges on the deeper, sandy loams. In the discussion which followed Mr. J. Aird suggested planting peaches and apricots at least 20ft. apart, and Mr. G. H. Holmes advocated the employment of a practical surveyor to take the levels on which the rows of trees were to be planted.

#### LAMEROO (Average annual rainfall, 16.55in.).

July 1st.—Present: 16 members and one visitor.

**DAIRYING.**—A paper on this subject was read by Mr. L. Sinclair. He dealt with the particular points of various breeds of cattle, and emphasized the necessity for proper attention and systematic feeding. There was no doubt, he said, that the majority of dairy herds in Australia could produce considerably more if they were regularly and liberally fed. In the matter of breeding he strongly advised the selection of a pure-bred bull. The best of the heifers by this animal should be selected to keep up the members of the herd. An interesting discussion followed.

#### MANTUNG.

July 4th.—Present: six members.

**HOMESTEAD PLANNING.**—A paper on this subject was read by Mr. J. P. Tonkin, who advised selecting a homestead site on an elevated position in the centre of the farm, with a slope to the north-east if possible. The house should face the north, and a garden or orchard should surround it. The stables should be about seven chains distant, and built north and south. He gave the dimensions of a stable which should be suitable, and outlined the arrangements of the chaff sheds and vehicular accommodation. The sites for the cow sheds and pig sties, he said, should be carefully selected, especial attention being given drainage. Messrs. L. J. Pearce, W. Stewart, A. H. Stewart, W. H. Lehmann, and J. N. Baker took part in the discussion which followed the reading of the paper.

#### PARILLA (Average annual rainfall, 16in. to 17in.).

July 30th.—Present: 19 members and three visitors.

**SORE SHOULDERS.**—In a paper on this subject Mr. C. E. Moyle recommended careful attention to horses' collars. These should be long enough to enable the ears at the top to meet when buckled, and sufficiently wide to obviate any wrinkling the side of the horse's neck. The hames must be properly fitted to the collar, and the draught adjusted. After a spell the horses should be put to work for only half of each day for the first week. During this time the animals should twice daily have their shoulders washed with cold water. They

should be carefully brushed in the morning, special care being given to the shoulders. In the event of a sore breaking out he recommended applying the following mixture—two cakes of black lead, mutton fat, and sufficient neatsfoot oil to keep the preparation soft, the dressing being applied before the animals were put to work. After work, veterinary vaseline should be applied. The sores most prevalent were—(1) Surface chafing of the skin, which healed fairly easily; (2) the sore after the nature of a boil, for which he recommended taking out the core and then applying vaseline; (3) the sore with a dry, hard scab, and a bruised appearance underneath which appeared on the side and occasionally on the top of the neck; from this the hard matter should be removed. He deprecated the practice of cutting or beating collars. It was only necessary to have them re-stuffed or relined when they became out of repair. In most cases the trouble was practically attributed to the collar, and he made a practice of having collars made to order for his horses. Another source of trouble was the animal's blood being out of order. In discussing the subject Mr. J. Lee attributed sore shoulders to ill-fitting collars and hames. Mr. J. A. Darby advised working animals lightly after a long spell, and washing their shoulders with water after taking off the collars. Application of neatsfoot oil and white lead should be made to the sores. Mr. E. J. Kinley recommended vaseline and oil at night and careful washing of the shoulders in the morning before working. It was also advisable to ease the collar on the shoulder when the latter was noticed to be tender. Mr. C. L. Dunstone, a visitor, advised having the collars periodically relined with good cloth and horsehair. It was preferable to secure new collars slightly on the tight side, as they would be found to stretch. Overloading was a very prevalent cause of the trouble. Mr. J. Roachock advised the use of a false collar where necessary, and applications of warm water and Condy's crystals to the sores. Mr. Camens advised washing the shoulders in hot water and using a mixture of sulphur, lard, and carbolic oil on the sores. Mr. M. Shannon recommended washing the shoulders with hot water, which encouraged a good circulation of the blood. Too heavy feeding with corn over-heated the blood, and tended to cause boils. This could be counteracted by feeding bran or giving salts. Messrs. S. and J. Gregory and H. G. Johnson also took part in the discussion.

#### PARILLA WELL (Average annual rainfall, 16in. to 17in.).

August 4th.—Present: 15 members and one visitor.

**AFFORESTATION.**—Mr. J. S. Ferguson contributed a paper. To provide shelter for stock he advised planting about half an acre with sugar gums, about 20ft. apart, with the exception of the outside rows, which should be 10ft. apart. The inside trees would develop into short-trunked, shady, wide-spreading growths, while the latter would tend to run up. After a few years they should be topped, and would then sprout out all over the trunk, and provide splendid winter shelter. The trees should be put into fallowed ground after a good rain in August. Trees could also be planted around the house and stables, and a plantation of from five to 10 acres in extent might be found profitable. The last named should consist of equal numbers of sugar or red gums, and Remarkable pines. The trees could be put in 8ft. apart, and would provide good straight timber. He strongly commended the practice of holding arbor days.

**SHRUBS FOR THE FARM.**—Mr. E. H. Teak contributed a paper, in which he urged members to plant shrubs around their homesteads. The tagasaste was a useful hedge plant, and one that would do well in this district. Stock were very fond of the cuttings. Shrubs could be safely transplanted in March or April, immediately after rain, or during September or October. This was too late for deciduous plants, however. The plants should be watered immediately after being transplanted, and this was best done by sinking a pierced kerosine tin or a drain pipe 2ft. from the trunk, and watering by means of this. Messrs. J. W. and J. E. Johnston and H. Inkster agreed that it was advisable to plant trees on the farms for stock shelter. The last named recommended putting them in the corners of the paddocks.

#### PINNABOO (Average annual rainfall, 16.74in.).

August 7th.—Present: 28 members and six visitors.

**FORMATION OF A VETERINARY CLUB.**—Mr. B. L. Harfield contributed an instructive paper dealing with the formation of a Veterinary Association for the Pinna-boo Districts. He pointed out at some length the advantages which would accrue from such an institution, and gave interesting details with regard to the organiza-

tion. The pros. and cons. of the matter were ably dealt with, and subsequently discussed by the members of the Branch, who, on the motion of Mr. J. Scales, determined to take steps to form an association forthwith. A committee of seven members was appointed to arrange the preliminary details and report at a general meeting of the residents of the district.

#### WYNARKA.

August 8th.—Present: 15 members.

**FALLOWING.**—The following paper on this subject was contributed by Mr. Colton:—"In our district early fallowing, i.e., commencing, say, on July 1st, thus enabling stumps to be cleared off the land, and preparing it for any necessary working is desirable. In some parts land to be fallowed is lightly cultivated before seeding to ensure germination; also to give the first rains a chance to soak in. Whether this will be a paying proposition in our district has to be proved. The main reason of fallowing is to conserve moisture. It has been proved that under normal conditions where the average rainfall is 20in., the moisture in fallowed ground between 6in. and 18in. deep equals more than an inch of rain over and above that at a similar depth in grass land. What this means will be readily understood when it is remembered that an inch of rain is equivalent to 100 tons of water per acre. It is advisable to have as much draft in the plough as possible in order to get rid of stumps. If the fallowed land is worked to a depth of 2½in. just before seeding and under proper conditions it must be in a better state to receive the seed than soil simply ploughed before seeding. A system of fallowing must go a long way towards sweetening the land and retarding growth of shoots, and eventually killing them. When the subsoil is only a few inches below the surface it is useless ploughing to a greater depth than 2in. or 3in., but when it is deeper down it is best to plough as deep as possible, provided the plough turns the furrow properly. We must not lose sight of the fact that the deeper we plough the more should the land be worked. The surface of the fallow should be gone over after good rains, and the best implement for this, to my mind, is the harrow. We cannot achieve the best results until the stumps are killed or removed." A good discussion followed this paper. Members generally agreed with Mr. Colton. Mr. C. Shultz was of the opinion that a good fire over land carrying a heavy growth of shoots, would sweeten it greatly, and kill a large number of the stumps.

**LAMEROO, August 1st.—STOCK AND CROP REPORT.**—Mr. Townsend mentioned that during the past month grass and feed generally had made little headway. Mr. E. J. Troubridge had noticed a decided improvement in the condition of stock generally, and sheep and young colts in particular.

**BAROMETER ON THE FARM.**—An extract dealing with this subject was read by the chairman, and following this members debated the reliability of this instrument.

**RENMARK, July 7th.**—The annual meeting of this Branch was attended by the Director of Irrigation (Mr. McIntosh), Mr. G. R. Laffer, M.P., and Mr. G. G. Nicholls, Chairman and Secretary respectively of the Advisory Board of Agriculture. Addresses were delivered by these gentlemen.

**WILKAWATT, August 5th.**—A paper read by Mr. H. V. Sprigg, of the Morphet Vale Branch, and published on page 88 of the March, 1914, *Journal*, was read by Mr. H. Pritchard. In discussing the subject, Mr. C. H. Cameron mentioned that he had grown various grasses in this district with good results. *Paspalum dilatatum*, Italian rye grass, and *Philaras commutata*, had been most satisfactory. Sorghum had also given good results.

**WYNARKA, July 4th.**—Members discussed the matter of manurial dressings to soils in this district. Mr. Shultz advised the application of 80lbs. of super. per acre. Farmers would notice the benefit in the succeeding year's covering of grass.

The matter of planting and pruning fruit trees was also discussed, Messrs. Shultz, Carlyle, and Beek giving much information in connection with this.

## SOUTH AND HILLS DISTRICT.

BLACKWOOD (Average annual rainfall, 27in. to 29in.).

July 20th.—Present: 15 members.

**BITTER PIT.**—The Hon. Secretary (Mr. C. G. Savage) read a paper summarising the observations and conclusions of Mr. D. McAlpine in his two progress reports upon the subject of "Bitter Pitt." He also quoted (by permission of the officer controlling the work) the as yet unpublished results of the research made at the Government Experiment Orchard at Blackwood for the season 1913-14 on the same subject. [As printing must necessarily be restricted under present conditions, arrangements have been made to supply any Branch of the Bureau in a fruit-growing district with a copy of Mr. McAlpine's report, on application to the Department of Agriculture, and for the time being to hold over the printing of the paper.—ED.]

BLACKWOOD (Average annual rainfall, 27in. to 29in.).

August 1st.—Present: 16 members.

**ORCHARD PLANTING.**—In a paper on this subject, Mr. G. W. Summers drew attention to the necessity for considering the matter of convenience in cultivating, spraying, and picking before planting. Varieties suitable to the different aspects and positions should be put in. He had found that Stone Pippin and London Pippin planted on high ground were practically profitless. Cleopatras should be planted on hillsides. All the late varieties, he thought, should be put in positions where there was abundance of moisture. As far as possible, it was advisable to place all apples, pears, peaches, &c., that flowered about the same time, together in the orchard. This facilitated spraying and pollination. Apples should be planted 20ft. apart on the septuple system, and apricots and peaches 24ft. The risk of fostering disease by planting in gullies was not great in this district, as the gullies were so open. In order to secure best results from cross fertilisation, the best plan was to plant the varieties not more than three rows wide. The falling of apricots at the stoning period was generally attributed to imperfect fertilisation. Some thought better results might be secured if the trees were irrigated at that period. Members considered it best to plant the trees with the stronger developed side toward the prevailing wind.

CHERRY GARDENS (Average annual rainfall, 35-03in.)

August 4th.—Present: 12 members.

**TIME TO PLANT FRUIT TREES.**—The Hon. Secretary (Mr. A. R. Stone) read a paper under this heading. One of the principal considerations, he said, was to lift or transplant at the time when nature was giving the trees rest. Establishing a vigorous root system was an important item. From experience he had learned that it was detrimental to plant the trees in holes which contained water, as the soil invariably settled down very hard in such cases. If the land required for planting were on the hillside and the variety of fruit early it was best to plant early. On level ground, where there was a stiff clay subsoil, and the drainage was not very good, trees of a late nature should be planted late. Stone fruit, such as plums, apricots, peaches, &c., needed early planting, but should not be put in on a very wet day, or too soon after heavy rain, as the roots were likely to pug. No time could be stated which would suit all parts of the country on account of the different climatic conditions, but each planter should study his own local conditions, and use his discretion as to when to plant. He recommended planting a few trees one year and the following year planting some of the same variety a little earlier and some a little later, the results being carefully noted. Since planting on these lines Mr. Stone had lost practically no trees.

## CLARENDON.

July 16th.—Present: seven members and two visitors.

A sample of Chou moulrier was tabled by Mr. Brookes. This had made luxuriant growth and yielded a considerable amount of green fodder.

The use of the cold waterspray for fruit trees was discussed, and members thought that this method would be worth trying if a sufficient pressure could be obtained.

Mr. A. A. Harper reported that portion of his fallow, which had been ploughed the third time, was showing the advantage of this treatment in the growing crop.

## FOREST RANGE (Average annual rainfall, 35in. to 36in.).

August 6th.—Present: eight members and three visitors.

**PRUNING.**—A paper was read by Mr. W. McLaren. The following is taken therefrom:—  
 “From general observations I am inclined to think we are not so careful or particular about pruning as we should be. I refer chiefly to the pruning of apple and pear trees. It is the trees in the bearing stage that do not get the attention they should. Most people seem to be afraid of removing too much fruit wood. One of the first things we should take into consideration is the variety we are dealing with, as there are some that we can afford to leave more wood on than others. For example, we can leave more lateral growth on the Jonathan and Rome Beauty apples than, say, Hoover or Winter Pearmain, and even these we can cut back closer as they get older. I have noticed a lot of trees carrying a mass of spurs all along the limbs as they get older, and close inspection shows these spurs to be a mass of buds. If they were all to set fruit it would greatly overcrowd the tree, unless thinning out were resorted to. By judiciously pruning the spurs, not only by thinning out, but also reducing the buds on the spurs left, the tree will be relieved of a very heavy blooming. It is necessary to prune for the growth of the tree as well, but I do not believe in the slaughtering that we sometimes see. It is wise to keep the main branches healthy by cutting back every year, generally cutting to an outside bud. Sometimes one branch will grow with more vigor than the others (this is very noticeable in the Jonathan), in which case it is a good plan to cut to an inside or side bud, leaving the second bud for the outside, and next year come back to that shoot, thus keeping the main arm with new wood at the end and bringing it back to balance with the others. Owners of large orchards are apt to rush through their pruning, and consequently there is too much indiscriminate cutting. I believe we should account for every cut we make, and be able to give a reason for making same. A healthy tree does not require the same treatment as one that is stunted; and a tree that is not growing well needs more thinning, as it usually makes more spurs than a vigorous grower.” In discussing the paper Mr. E. Rowley said that there was a tendency to leave the laterals too long on some varieties, such as the London Pippin, but on Jonathan it was advisable to leave them long. On Rome Beauty short spurs should be left. Where he had thinned the most he had secured the best setting of fruit.

## MOUNT BARKER (Average annual rainfall, 30-93in.).

August 5th.—Present: 46 members.

**DRAINAGE.**—The Hon. Secretary (Mr. J. E. Smith, B.Sc.), read a lengthy paper on the subject of drainage. In the discussion which followed Mr. J. Scrymgeour said that tile draining was most costly. The cheapest and best type appeared to be the old Scotch drain. In that a trench 3ft. deep was dug, care being taken to have a good bottom. Stones were planted edgewise and covered with flat stones; these were covered with stones on edge for about 8in. then 6in. of tussock grass was piled on. The trench was then filled with earth. The type was largely used in America. Mr. J. Frame said the drains laid down in his father's time were as good as new now. A deep trench was cut through the boggy land; stones were laid down, then straw, and the trench then filled in with earth. Mr. Coppin preferred furze to straw. Mr. Simper was averse to the use of slabs. Mr. Fidler thought stone drains generally blocked. Pipes were laid close on an even bottom and never silted up. He instanced tile drains in Western Australia and New Zealand. If land was irrigated it must be drained. Mr. Bell mentioned an old Scotch drain laid down 40 years ago still doing good work. Mr. Scrymgeour mentioned an interesting plan for watering small gardens. The drain pipes were perforated and laid about 18in. deep—a kerosine bucket was used for the inlet. With surface cultivation the moisture was conserved.

## MOUNT COMPASS (Average annual rainfall, —in.).

July 11th.—Present: 13 members and three visitors.

**POTATOES.**—Mr. M. Jacobs contributed a paper on this subject. Potato culture, he said, had occupied a good deal of attention in this district. As the area of new swamp land available became less so the yield decreased, as the “old” land produced smaller crops. In his opinion in the future they would have to depend largely on growing their potatoes on what were considered inferior soils, and this necessitated better methods. On the rich swamp land the crop might be grown for a number of successive years. He had known land to be cropped 14 years without a rest and grow fair crops, but on the poorer soils, such as the loams and sandy flats, two potato crops with the present methods

seemed to exhaust the soil. In preparing the land he advised fallowing or ploughing at least six months before planting to a depth of 6in. to 12in., according to the soil. This should be worked to a fine tilth, as cultivation could not be done once the crop was planted. The choice of seed was of great importance. Small seed (from nine to 12 to the pound) from a real good crop could be planted with safety. From experience he found a rough-skinned, overgrown, and mis-shapen potato the best. The smooth tubers, as a rule, came from a small crop, and were inclined to run out. Seed should be secured two or three months before planting and greened. A floor of grass, tree leaves, &c., was excellent. This did not absorb moisture. It should be about 3in. thick, the potatoes being placed in a single layer and covered lightly with bushes; just sufficiently to protect them from frost, but not excluding the light and air. Rain would not hurt, but seems to improve them. Short sturdy shoots would develop. Any that were weak should be rejected. It was better to get a few extra bags to make up for those discarded. If planting out sets care should be taken not to destroy the shoots. The distance between the sets depended on the variety. Snowflakes required 30in. by 24in., Up-to-date 24in. by 16in. It was better to give more room than to cram. The one variety should not be planted in the same land two years in succession. For the swamps he favored Snowflakes, Carmen, and Up-to-dates, and for sandy and loamy soil, Redskins. In the absence of farmyard manure he favored bonedust, applying up to half a ton per acre on the swamp, but the potato manure was better for loamy soils. Planting could extend from October until January, and could be a little earlier in gullies free from frost. Mr. Peters advised selecting seed true to type. He knew one gardener who grew good crops continuously for 30 years by thus selecting from his own crop each season. The Hon. Secretary reported that a number of growers at Nangkita and along the lower end of Mount Compass swamps had advised that the disease which had played havoc with the Mount Compass crops last year was bad this year in their portion of the district, and threatened to drive a number of growers out of the business. The disease was investigated last year by Professor Osborn. Several members advised every grower to study that report, it should give any practical man a grip of the trouble (see August, 1913, issue, page 19). Mr. Hutton said it was essential to plant clean seed. A grower in Victoria had used corrosive sublimate dip and sprinkled sulphur on the implements and along the furrow with the sets with excellent results. His experience this year was that clean seed from another district in new ground gave a clean crop; in old ground, a comparatively clean crop; seed selected from his own crop last year gave a fairly clean crop this year; seed not selected gave a badly diseased crop. Mr. Slater thought it better to select from his own seed than risk bringing in other diseases with seed from other districts; he did not think there was much danger of contamination from the soil. Clean self-sown potatoes had grown this year on spots that were carrying badly affected crops last year. He considered this due to the soil being open longer to the sun. Mr. Skews had been careful in selecting his seed. Where he worked the ground with the plough, his crop was comparatively clean; where he dug the ground, the disease was bad. Mr. Horner advised thorough draining. Water helped to spread the disease if the crop were irrigated by flooding. It was most important to rake up and burn the old tops. Any good they might do as manure was not to be compared with the harm caused by their carrying over disease. Generally, members agreed that in order to stamp out the disease it would be necessary to plant only in clean ground; plant only clean seed, for at least two or three years. To do this meant that the bulk of the potatoes would have to be grown on the lighter soils for a while. All members agreed that Carmen was a good variety for the lighter soils, but five considered Bismarok a heavier cropper. The Hon. Secretary thought that possibly the failure to grow more than one or two crops on the lighter soils was due to exhausting the potash. Samples from the experimental plots indicated that the potash content was rather low for potatoes. Professor Lowrie had recommended wood ashes and some private experiments indicated that this was beneficial but not equal to sulphate of potash.

#### MOUNT PLEASANT (Average annual rainfall, 26-87in.).

August 7th.—Present: six members.

**POULTRY.**—In a paper dealing with this subject the Chairman (Mr. H. A. Giles) said the conditions under which poultry were generally kept on the farm were not creditable. He recommended the enclosure of about one acre of soil of a gravelly nature, and in the centre of this erecting a galvanized iron shed not less than 20ft. wide and 10ft. deep. The back should not be less than 6ft. high, and the front 5ft. high. It should face the east, the front being enclosed with netting. The floor should be concreted with six parts gravel and one part cement. Movable roosts and nests should be provided. Six inches below the perches matchboard dropping boards should be provided. The excreta should

be removed weekly, and deposited in an old tank or cement cask for use as manure. Once at least every three months the nests and perches should be removed, and washed in hot suds, lime water, or sheep dip. Shell grit or fine gravel should always be available. Lucerne, kale, cabbage, &c., should be fed to the birds daily. Eggs should be gathered once every day. In reply to a question, Mr. Giles said he had 57 hens and pullets, 11 cockerels, one turkey, and five geese, and he gave these half a gallon of wheat in the early morning, four pints of bran, and four pints of pollard scalded and mixed later on in the morning; cut greenfeed at mid-day, and half a gallon of wheat at night.

**IRONBANK, August 1st.**—The Hon. Secretary (Mr. W. H. R. Coats) read a short paper dealing with the cure of leaking cow's teats.

**KANMANTOO, August 5th.**—The Horticultural Instructor (Mr. Geo. Quinn) gave a pruning demonstration at the residence of Mr. J. Downing before a large number of members and visitors. In the evening this officer also delivered an address, which was highly appreciated.

**LONGWOOD, August 1st.**—**HOMESTEAD MEETING.**—A meeting was held at the homestead of Mr. W. H. Hughes. Inspection of the fodder crops revealed the benefit to be derived from liberal dressings of bonedust to barley and oats.

**MEADOWS, August 4th.**—**POTATOES.**—A paper written by Mr. R. Provis, of the Yallunda Branch, and published on page 1204 of the *Journal*, was read and discussed. Mr. E. B. Ellis said old seed potatoes gave better results for late planting than new tubers forced to shoot. He made a practice of soaking the potatoes in water for two or three days to kill worms. Mr. W. Nicolle considered from 12in. to 14in. sufficient distance between the sets.

**EXHIBITS.**—Mr. G. T. Griggs tabled six varieties of apples.

**PORT ELLIOT, July 18th.**—**MINERAL SUPER.**—A paper on this subject was read by Mr. J. Chibnall. He dealt with the effect of mineral super. on soils, and expressed the opinion that farmers in mallee land would find it necessary to keep sheep in order to ensure payable returns from some of the lighter soils.

**STRATHALBYN, August 11th.**—An interesting paper on the horse was read by Mr. A. Beviss. A lengthy discussion followed.

## SOUTH-EAST DISTRICT.

### COONAWARRA.

July 23rd.—Present: nine members.

**MANURING ORCHARDS AND VINEYARDS.**—Mr. R. Lea read a paper. He mentioned that he had made a practice of manuring vines and fruit trees for the past 12 years and the result had been regular crops and an abundance of good vigorous wood. As a general rule the manures to be applied to fruit trees should consist of phosphates and potash, with a small proportion of nitrogen. Well rotted stable manure should also be applied, or in the absence of this, straw ploughed under in early winter would be found beneficial. Ploughing in peas or vetches in the flowering stage would add nitrogen to the soil. Potash developed a very fine color on fruit, especially apples. The practice he adopted was to vary the manurial dressings; the first year applying super., second year lewt. per acre of bonedust, and the third year bonedust and super. mixed. It was also essential that the soil should be cultivated thoroughly.

**FRANCES (Average annual rainfall, 20-74in.)**

August 20th.—Present: nine members.

**GREEN FODDER CROPS.**—A discussion on this subject was initiated by Mr. Meehan. He had a fine patch of green field peas, 2ft. 6in. high, on which he had been feeding several aged ewes. They ate the green well, and had put on condition in a short while. He believed larger paddocks could be very profitably cultivated with field peas. Mr. Harold considered that a stubble paddock to be "left out" paid much better seeded with oats;

the sheep did extra well when turned on an oaten field for a few days occasionally, and the lambs in particular did well. Oats were cheap, easily seeded, were hardy, and grew well. The Chairman (Mr. McGillivray) considered that kale was superior as green feed. It grew well in any soil, lived for years with hard feeding, and responded to light showers freely. All stock liked it. The Hon. Secretary (Mr. Feinaler) had tried two large paddocks with English and Italian rye grass, but they did not appear to be the best, although a good deal of green feed was produced. In small patches lucerne had been reported as doing extra well, and he considered that far larger plots of this valuable green feed should be put in. Japanese millet had proved to be an excellent green feed. During February, March, and April, and in the dry spell of 1912, it grew well, and was of great value as sheep feed. Reference was made to the good feeding properties of *Paspalum dilatatum*, but no member had been successful in its propagation.

#### GLENCOE (Average annual rainfall, 33.84in.).

August 3rd.—Present: eight members.

CHAFF FOR FATTENING STOCK.—In an address on the subject of fattening cattle on chaff, Mr. H. A. Agnew said that when chaff was at such a low price as it had been of late it was necessary to devise some means to use it to the best advantage, and he had proved that by buying and fattening cattle the return for the chaff could be made to equal £3 per ton. Feeding hay to stock was wasteful, but by using burnt-out logs for feeders, and having a chaffcutting plant on the farm, chaff-feeding could be carried out economically, and there was no waste. A good deal of chaff was wasted when self-filling feeders were used, as the cattle, when they had enough commenced to toss the feed about. He put out chaff early in the morning and in the evening, when, as a rule, the wind was lightest. There was little profit in buying cattle in forward condition; it was better to buy them poor. He had fattened speyed cows and heifers in poor condition in three months, and ordinary stores in six weeks. However, they varied considerably, and a great deal depended on the class of country from which they were derived as to how long it took to fatten them. In reply to questions Mr. Agnew said he had used the ordinary short cut in chaffing, but a long cut would be preferable. He was keeping up to 70 or 80 head of cattle in small paddocks of about 20 acres, so that the land should be enriched considerably. The hon. secretary (Mr. G. F. Ferguson) said that in addition to the direct return from chaff feeding, there would be a further return in the increased fertility of the soil on account of the manure from the stock. He had fed chaff to his sheep during the whole of the winter, and was confident that it paid well; the sheep did not scour to the extent that they did when fed on greenfeed only. He recommended feeders made from super bags with the sides sewn round 6-gauge wire as being very serviceable. Mr. J. Dow mentioned that a neighbor of his had fed barley to sheep, and estimated that by this means it returned 3s. per bushel. While this neighbor had sold his sheep as "fats," his (Mr. Dow's) were still "stores."

#### MOUNT GAMBIER (Average annual rainfall, 32in.).

August 8th.—Present: 16 members.

PREPARING WOOL FOR MARKET.—A paper on this subject was read by Mr. J. F. Hollo-way. He dealt more particularly with the smaller clips of farmers and small graziers. "It was more tedious to group the various classes found in small clips than it was in big sheds," he said. "Care and conscientiousness in the 'get-up' was the main secret of success. Skirting the fleece required skill and care. No rule could be laid down as to the depth to skirt. The man in charge would be guided by the conditions of the wool in this respect, and should see that no more than was necessary was taken off. In large clips the general practice was to 'pick' the pieces, which practically amounted to skirting. The bolly wool was similarly treated. He did not advocate picking pieces, but favored classing them for quality. Classing should be done evenly and into the largest possible lines, hence the necessity in small clips for grouping a reasonably wide range. A crossbred clip must be classed mainly on quality, whilst in Merino, where the quality was much more even, the principal feature to be considered was condition, i.e., the amount of grease, &c., that the wool carried. The length of staple, too, should be taken into consideration in classing. Any fleeces that were too fine or too strong for the average quality should be kept separate, and if there were less than four or five bales of such, growers would be well advised to have such lots bulked at their stores." He concluded by recommending attendance at the School of Mines to young men who desired to acquire a thorough knowledge of wool.

## INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

### STOCK INQUIRIES.

(Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"R. E. C.," Naracoorte desires treatment for horses which eat very greedily but do not put on good condition, often pass small quantities of urine, and easily tire.

Reply—Worms of various sorts. Give two tablespoons of Fowler's solution of arsenic once daily in the food for a fortnight, stop same time, repeat another fortnight. Also give in a little bran once a day a teaspoonful of sulphate of quinine. Keep this up daily for a month.

"J. A. H.," Tintinnarra, asks treatment for colt constantly rubbing against fences; hair coming off; looks like mange.

Reply—Possibly mange, but more likely lousy. Stand him in sun for an hour, then lather all over with soap, leave to dry on; a few hours after wash off with a 5 per cent. solution of coal tar disinfectant such as cyllin; next day wipe over with benzine one part, any cheap oil five parts; repeat if necessary in a week; if it is mange, repeat twice; if lice, which you will be able to find, repeat benzine and oil once a week for a few times.

"C. D.," Belalie North, had horse which started pawing and blowing heavily; then constantly lying down and seemed in pain. Given mixture of salt, ginger, and carbonate of soda, but died 12 hours after attacked.

Reply—The mixture was all right, but it is better not to mix soda and saltpetre. The red jelly-like appearance of the big bowel was indicative of what is termed blood colic, which is inflammation of the colon, generally due to the movements of blood worms. Aconite would have been of service.

"W. P.," asks information concerning lambs which became stiff after tailing and dragged their hind-quarters when moving. They eventually recovered.

Reply—Blood poisoning causing swelling of glands under loins.

"C. A. H.," has draught mare, which is in low condition and slobbers her food badly, even when eating green stuff; her coat is dull and staring.

Reply—The symptoms point to defective teeth and worm abscesses in the stomach. If a teaspoonful of baking soda in the feed twice daily for a fortnight does not lessen the slobbering it would probably be cheaper to truck the mare to a qualified veterinary surgeon in Adelaide than to call him out to see to the teeth.

"H. S. C.," Mount Compass, asks if there is cure for a cow which has been blind for six months, possibly caused through eating yacca.

Reply—Cows do go blind from eating yacca, and very possibly this is the case here; but after nine months a cure is very doubtful. A heaped teaspoonful of this powder twice a day in feed might help—equal parts of powdered nux vomica, sulphate of iron, sulphur, sugar; also twice a week dress the eyes with 1 per cent. solution of nitrate of silver.

"L. J.," Riverton, asks treatment for horse recovering from severe attack of influenza which has a hard swelling on neck behind jaw; this has been bathed with hot water, but hair and skin is peeling off.

Reply—The swelling is an enlargement of the gland; if the skin had been sound it would have been well to have rubbed in daily a little mercurial ointment, but as it is, probably camphor ointment will be better; camphor one part, lard four parts.

"J. G.," Berri, has aged mare which was served last season but not in foal; she passes a slimy discharge frequently, and is losing condition on hay but did well on lucerne. She has a lump on near side of jaw and slobbers a good deal.

Reply—Quite possibly the teeth are defective, and in an old mare likely to remain so; but more probably there are worm abscesses in the stomach causing slobbering. The position of the swelling in the jaw is not precise enough to say what it is; possibly a tooth-root abscess; if movable on the side, a cheekstone (*salivary calculus*). The discharge points to catarrh of the vagina, and if she is put to horse this season she should be swabbed out before service with a pint of warm water in which a teaspoonful of baking soda has been dissolved. She will probably improve in all respects if she gets a teaspoonful of baking soda in her food twice a day for a month, and once a day for the same period 15 drops tr. pulsatilla just put on her tongue with a little molasses or pollard.

"H. G.," Victor Harbor, asks advice concerning cow which has been out of sorts for a fortnight. Her jaws and throat swell at intervals, and lower jaw quivers; appetite is good, and also condition.

Reply—Difficult to diagnose without seeing the case. Improvement would probably follow this treatment—Once daily rub into the swelling a bit of mercurial ointment the size of a walnut and give in the feed 1oz. flowers of sulphur for 10 or 14 days; for the same period put on the tongue twice a day 20 drops vet. tr. nux vomica. The trouble is connected with the glands in the throat.

"E. J. S. A.," Coonawarra, asks cause of death of cow in season which, after being driven eight miles, was very tired, and laid down with tongue out; died few hours later. *Post mortem* revealed "blobs" in lungs.

Reply—The symptoms are those of over-exertion. The blobs were hydatid cysts (*Echinococcus multilocularis*) which, in some degree, were contributory to death, but not the immediate cause, which was probably pulmonary apoplexy, not poison.

"J. E. S.," Bordertown, asks advice concerning draught stallion suffering with greasy heels.

Reply—There are several kinds of eruptions which go under the name of greasy heels, some of which arise from unhealthy blood and may be called hereditary; others arise from neglect, and are often parasitic. However, in a young animal benefit would be obtained from a 5 dram aloes ball, followed by  $\frac{1}{2}$ oz. of sulphur in feed once daily for a fortnight, and the daily application of a little of the following lotion:—Sulphate of zinc  $\frac{1}{2}$ oz., subacetate of lead  $\frac{1}{2}$ oz., methylated spirit  $\frac{1}{2}$  pint, water  $\frac{1}{2}$  pint. Light food, preferably green, good grooming twice daily, do not wet legs except with lotion.

"H. B.," Port Pirie, has horse suffering from wire wound of six months standing. There is scaly swelling, and occasional discharge of watery fluid and blood. He asks for treatment.

Reply—The present conditions arise from previous granulation, but if the wound is dressed daily with a little lotion of iodine, 1 dram dissolved in 1 pint methylated spirit, and at night is wrapped round with a good wad of cotton wool retained in place by a tightly applied linen bandage, improvement will soon set in.

"A. B." has lost several horses through felt balls. They are common in sheep running on cottonbush country, but he has never before known horses affected. There is no green feed on his land, and he asks how to treat other horses that may become affected.

Reply—The only thing likely to shift these is the one mentioned unobtainable, namely, green feed; if the bowels can be normally distended by it the smaller balls are passed, otherwise purging and back raking have to be depended on, and are not satisfactory. When they are in the hind gut, although unreach-able, sometimes an injection of 4 ounces of glycerine will bring them out, but not always. One grain of sulphate of eserine injected into the jugular vein sometimes removes them; if not, it kills the horse, and really requires adminis-tering by a veterinary surgeon to prevent all the horses treated from dying.

One dram of chloride of barium might be given in a little molasses on the teeth to a horse of no value, as an experiment; it is as likely to kill as cure. They cannot be dissolved by drugs.

### DEVELOPMENT OF GRAIN IN HAY CROP.

"H. P. McC.," Yabmana, asks if the grain draws any vitality from the straw after having been cut for hay?

The Director of Agriculture states—"In cooler countries in which wheat is harvested with the mower and binder and subsequently thrashed, it is generally admitted that if the crop be cut slightly in the unripe stage the grain matures more satisfactorily in the stook than if allowed to acquire complete maturity as a standing crop. It may be assumed, therefore, that to a certain degree the grain may continue to draw on the straw for its development for a limited period of time, *i.e.*, so long as the sun has not completely dried up the grain and straw. Under our conditions summer heat is, as a rule, very intense, even at haymaking time, and I believe that in most cases the rapidity with which a hay crop dries up will in most cases interfere with any appreciable development of the grain."

### FOOD VALUES OF GRAINS.

"W. T. S.," Mount Barker, asks to be informed as to the food values of various grains.

The Director of Agriculture in reply states—"While a comparison between concentrated foods, such as the various grains, is legitimate enough, quite another standard must be adopted for comparing less concentrated food, such as hay, straw, &c. At best these comparisons are merely relative, and liable to vary, not only with the quality of grain used, but with the special individual aptitudes of livestock to which it is fed. The only possible general standard of comparison is based on the general 'fuel value' of the foodstuffs. The foodstuffs you mention may be compared as follows, on the understanding that a pound of wheat has a fuel value of 1,350 calories or units of heat (*i.e.*, quantity of heat necessary to raise 1 gram of water by 1° Centigrade). In this table I have assumed a bushel of wheat to have a value of 3s. 6d.

*Table showing Relative Food Values of Various Grains, Wheat being equal to 3s. 6d. a Bushel.*

|              | Fuel Value.<br>Calories per lb. |    | Value per lb.<br><i>d.</i> |    | Value<br>per Bushel.<br><i>s. d.</i> |
|--------------|---------------------------------|----|----------------------------|----|--------------------------------------|
| Wheat .....  | 1,350                           | .. | 0.70                       | .. | 3 6                                  |
| Pease .....  | 1,550                           | .. | 0.80                       | .. | 4 0                                  |
| Beans .....  | 1,500                           | .. | 0.78                       | .. | 3 11                                 |
| Maize .....  | 1,500                           | .. | 0.78                       | .. | 3 11                                 |
| Barley ..... | 1,280                           | .. | 0.66                       | .. | 2 9                                  |
| Oats .....   | 1,200                           | .. | 0.62                       | .. | 2 1                                  |
| Bran .....   | 1,100                           | .. | 0.57                       | .. | 0 11                                 |

The following examples will establish a similar comparison between less concentrated foodstuffs. I have taken clover hay as a standard, and assumed it to have a value of £1 a ton.

*Table showing Comparison of Values of Less Concentrated Foodstuffs.*

|                   | Fuel Value.<br>Calories per lb. | Value per lb. | Value per Ton. |
|-------------------|---------------------------------|---------------|----------------|
|                   |                                 | d.            | s. d.          |
| Clover Hay .....  | 990                             | .. 0.11       | .. 20 0        |
| Oat straw .....   | 720                             | .. 0.08       | .. 14 11       |
| Grass .....       | 300                             | .. 0.03       | .. 5 7         |
| Bean haulms ..... | 760                             | .. 0.08       | .. 14 11       |

It should be remembered that figures of this kind can never be taken as 'absolute' in their incidence."

### HORTICULTURE.

Mr. J. McClure, of Dunedin, New Zealand, has written to Mr. Quinn (Horticultural Instructor) for information concerning the planting of apple trees to secure cross-pollination.

Mr. Quinn's reply is as follows :—"The subject of cross-pollination is much discussed by fruitgrowers here, but as far as definite scientific investigation goes, we have only reached the first stage, viz., noting the periods of blooming of the varieties—all the rest is conjecture. In so far as my general casual observations go, I note where different varieties of the same fruit trees are growing together in a mixed up fashion the yields certainly appear to be more regular, but I cannot recall one orchard in respect to which this observation has been made which has not received exceptionally good treatment, such as systematic rather than severe pruning, careful spraying, and excellent tillage. So that the mixture of varieties may not, after all, prove the sole reason for the more regular yields in these places. If it is of any use to you, I may state that here in Australia Jonathan shows good bloom from about October 10th to 18th; Rymer, October 18th to 26th; Sturmer, October 12th to 24th; Five Crown (London), October 28th to November 3rd; and Delicious (one year's record only), October 24th to 28th. If I were planting commercially I certainly should plant the sorts which bloom simultaneously together in double rows, so that if a further extension of the investigations into the question of cross-pollination proves there is nothing to be gained, you will lose nothing more than the cost of replanting, as double rows are as readily and economically sprayed or harvested as trees in continuous blocks would be. Of course, I have not entered into the subject of probable variability of the soils in the orchard. Here we have dry localities and wet ones, and all the sorts you mention are suited to our wetter localities."

## WOOL AND THE WAR.

The following appeared as an editorial in *The Pastoral Review* of September 16th :—

“ But little more than a month ago the outlook as regards values for the Australasian wool clip of 1914-15 was never brighter. It was generally admitted that the world's demand for wool had overtaken supplies. It is an undisputed fact that the world's population and purchasing power has been expanding for some years past, whilst the better employment of labor at increased wages, together with the enlightenment of the masses, had resulted in an increased per capita demand for woollen clothing as against cotton, shoddy, and other less healthful and less comfortable substitutes. Despite the fact that there had been a particularly stubborn fight against any enhancement in raw wool values, prices continued to advance, and those who played the ‘ bear ’ game lost heavily simply because the unconquerable natural laws of supply and demand were against them. Never before were British manufacturers so hopelessly out of their calculations, and so palpably scored over by their Continental competitors, who bought a great weight of the Australasian clip of 1913-14, whilst the Britishers either looked on in apparent bewilderment, or put their heads into the noose of insolvency by selling forward big weights of wool in its various forms, which they did not possess, at prices much below the current prices of the day. Notwithstanding strong bear tactics, and the general hand-to-mouth policy of consumers in all countries wool values rapidly advanced until at the commencement of the new statistical year, at the beginning of July, fine wool, which had so long been favored by fashion, stood at a level of values which had not been exceeded since the year following the termination of the Franco-Prussian war, viz., 1872. Certainly the all-round average of all classes of wool was higher during the boom of 1899, but not so Merinos. The boom of '99 was very largely brought about by speculation, whilst the high prices of a month or so ago resulted despite the total absence of speculation, and were fully justified by a careful consumptive demand having overtaken supplies, and this despite the fact that the past Australasian clip showed an increase of over 300,000 bales. What, then, was the position of wool before the international explosion in Europe a few weeks ago ? It was this : Stocks of wool in all its forms were much below normal, consumption has overtaken demand, the international and financial atmosphere appeared to be favorable to trade expansion, and a decreased production of wool, owing to adverse seasonal conditions in Australia and South Africa, was inevitable. Wool values were high, but in no wise excessive. Buyers from all nations had either started or were about to start for the Australian centres, possessed with orders to buy wool and the where-

withal to back their demands. The trade generally admitted that prices for Merino and fine quality crossbred wools were more likely to advance than decline, and that other descriptions should hold their own.

“What has happened? Within a week or so the great countries of Europe were involved in the greatest and bloodiest struggle in the history of the world. The magnitude of the struggle is so great that nations and peoples are stunned by the suddenness of the thunderclap. Trade becomes dislocated, and it is a wonder that it is not killed. The great wool manufacturing districts of Europe, which are clustered on the borders of Germany and France, and in Belgium, have become the cockpit of battles. The great wool consumption of Europe is cut off as with a knife, and the whole world's financial position is thrown into turmoil. From a wool point of view the situation is no doubt unprecedented. The position requires to be soberly faced, and when this is done by those interested—and practically everybody in Australasia is interested in wool—it must be admitted that, bad as it is, it might be worse. After all there is a silver lining to every cloud. During the year ending on June 30th last the Continent of Europe purchased no less than 65 per cent. of the total Australasian wool clip, and over a period of ten years has taken slightly more than one-half of the Australasian production of wool, France, Germany, and Belgium being the principal countries of consumption; and of more recent years, be it noted, Germany had lain in the greatest stocks. Now, one would naturally suppose that war, more especially a great European war waged in the wool manufacturing districts, would spell havoc in the raw wool market, but history shows that during the wars of the past there has been a tendency for wool values to advance. Take, for instance, the great Franco-Prussian war, 1870-71, which was waged amongst the great wool manufacturing centres of Continental Europe, and what do we find? Prior to the outbreak of war the average value of a bale of colonial wool in London, *i.e.*, for the year 1869, was £15 15s. In 1870 it rose to £16 15s.; in 1871 the average was £20 10s.; whilst the year following the declaration of peace witnessed the high-water mark in wool values, the all-round average per bale of the 743,000 bales of Australasian and Cape wool sold in the London market being no less than £26 10s. per bale, whilst for the three following years the average ranged from £22 5s. to £24 5s. per bale. During the United States civil war, 1861-65, the average value of a bale of colonial wool in London ruled at from £22 15s. to £24 15s. During the Russo-Turkish war, 1877-78, at £18 15s. per bale. During the first year of the Boer war, 1899, the general average value of wool rose to the highest level reached since the year following the Franco-Prussian war, but the rise being mainly brought about by wild speculation, the following years witnessed the most sudden collapse in wool values ever recorded. During the Russo-Japanese war, 1904-5, the average value of wool in London advanced by £2 per bale, the average price in 1905 being £15 15s., as against, for instance, £11 15s. for the year 1902. Past history shows, therefore, that great wars

have tended to enhance wool values, why, therefore, is there any cause for panic at the present time? The answer of the pessimist will be that the present war is unprecedented in the history of the world; and so it is, but so is the statistical position of wool. The world's trade is being torn to shreds, and finance terribly upset, &c. The Franco-Prussian war cost 1,900,000 lives and £1,250,000,000. There were less men to spare and less money in the world 40 odd years ago than is the case to-day, and it is almost a certainty that there will be fewer men slaughtered, and probably less money squandered, in the present struggle, though the former supposition is more likely to be borne out than the latter. Undoubtedly there is every justification for extreme caution in the wool trade, as in all trades, but we do not admit that there is any justification for undue pessimism as regards the outlook for wool, the staple product of Australasia. After all, Britain remains the undisputed mistress of the seas, the trade routes of the world are open, rates of insurance, including war risks, are but 2 per cent. from Australia to Great Britain and United States of America, and the Bank of England rate of discount stands at but 5 per cent. It has often been higher in times of peace. Certainly the great wool-consuming countries of France, Belgium, and Germany cannot be expected to buy much, if any, wool directly during the currency of the war, and even after the declaration of peace it will take years to straighten up the great wool and other industries of those countries; but the rest of the world is free to trade with us, and looking to the more immediate future, the enormous armies in Europe require to be well clothed for the coming winter campaign—a process which will take a great quantity of crossbred wool. It is known that stocks of wool in all countries are below normal, and now that wool is admitted duty free into the United States of America, the greatest of all wool-consuming countries, a much greater quantity of our wool is required for that country than usual. The increasing population of the world must be clothed, and from a wool producer's point of view, it matters little in what country the manufacturing process takes place. It is known also that the coming year will disclose a serious falling-off in wool production. What reason, therefore, to be pessimistic as regards the future market for wool? It is admitted that since the great crisis came upon us an attempt to hold sheepskin sales in Melbourne and other centres resulted in a decline of from 40 per cent. to 50 per cent. in values; but sheepskins, though full-woolled at this season of the year, are a different proposition to wool, in so much that they cannot be held with impunity owing to their being subject to deterioration in value due to weevils. Wool is a commodity which is comparatively easy to store, and which shows but a very small intrinsic decline in value even if kept in its raw state for some years. In conclusion the writer would venture to express the opinion that there is no justification for any collapse in the wool market. Some considerable decline from recent very high values will have to be expected, more particularly for fine wools such as have

been relatively dear, but there is no reason for a slump, and a slump will not occur if the Australasian growers decide to 'sit tight,' wait until the world must have their wool, and not, as unfortunately has been the custom of late years, force the whole year's production on the market in a few months, regardless of whether the manufacturing end of the industry is prepared to purchase and pay, or otherwise. No doubt there will be a certain proportion of owners who must realise upon their clips with as little delay as possible, but the great bulk of our woolgrowers have sufficient 'inside fat' to exist on for some time, and if a sufficient number decide to hold on to their clips until such time as a big consumptive demand develops, they will be well rewarded for their patience. Australasia holds the key of the wool world, and should keep the door locked until prices are forthcoming such as are justified by the statistical position, by past history, and as are required to recoup producers for the bad times which they must in the meantime experience."

## THE WAR AND FOOD SUPPLIES.

### RECOMMENDATIONS OF FEDERAL ROYAL COMMISSION.

The report of the Commonwealth Royal Commission on Food Supplies contains much of great interest to the primary producer. Below will be found some of the recommendations of the Commission (Messrs. A. Deakin, Dugald Thomson, and G. H. Knibbs) dealing with meat-canning and increasing the wheat area.

#### EXPORT OF FOODSTUFFS.

No. 1.—As safeguarding the restrictions already proclaimed, we beg to advise that, inasmuch as a ship carrying foodstuffs may, after getting its clearance, leave Australian waters and proceed to any place whatsoever, it seems essential that no such ship should be allowed to depart without guarantees being given to the satisfaction of the Government that she will not commit a breach of proclamation.

#### MEAT-CANNING.

No. 2.—In view of the fact that large quantities of tinned meat are likely to be wanted for troops in connection with the present war, and that unless special orders be given the canning season will soon terminate, it is suggested that inquiries be made as to whether the British Government is prepared, on account of the circumstances, to place orders, and to what extent and for what period. If that Government is unable, it is recommended that the

Commonwealth Government might nevertheless make arrangements for canning factories to put up considerable quantities of tinned meat for export, and it is understood that the class of cattle suitable for this purpose is probably available. Any possible loss which might be incurred will probably be negligible when the importance of anticipating the need for supplies is kept in view. It may be added that work of this kind tends to alleviate unemployment, which threatens to become widely extended.

#### INCREASE THE WHEAT AREA.

No. 3. Prolongation of the war.—If, as is quite possible, the war be prolonged for a year or more, the pressure on food supplies is likely to become acute. The full effect will be felt of the destruction of and failure to reap a portion of this year's crop in France, Belgium, Germany, Austria, and, to a lesser extent, Russia; also the expected shortage in the present Canadian crop, and the certain, perhaps large, shortage in the growing Australian crop. These effects, and the fact that belligerents will have a diminished opportunity of planting and cultivating the next crop, will probably not be nearly counterbalanced by the expected excess of the crop just harvested in the United States. The feeding of Great Britain and the allies is of vital importance if victory is to be achieved at the end of a prolonged war. It is therefore strongly recommended that unless the end of hostilities is reached before the time for planting next year's Australian crops, steps should be taken to largely extend the area put under wheat, and other crops, which, while not so suitable for export as wheat, may be used for home consumption to relieve wheat for export. To that end Australian landholders should be urged and induced (their patriotism should render compulsion unnecessary) to plant largely extended areas. As a security to them, if such be needed, the British and Australian Governments, acting in consort, might engage to take up to a certain quantity at a maximum price of so much, down to a minimum price of so much, or at the market price, between. If that so taken were paid for by the Commonwealth Government, the financial adjustment could be made without any strain on the latter and without actual remittance by the British Government paying interest in London on the Australian debts, the States refunding to Commonwealth in Australia. Employment would be assisted by such an enlargement of production. Meantime it is recommended that the States Governments and their Agricultural Departments be urged to take steps to enlarge the planting, not yet completed, of maize and potatoes. One or both of these valuable crops bids fair to be short, and to require importation. This will be doubly unfortunate in that the importation would prove costly to consumers and mean loss of employment in Australia, while the shortage would entail a greater local call on the wheat crop, instead of its relief for the feeding of the British and allied troops, on which, if the war be prolonged, everything will depend.

## ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, September 2nd. Present—Mr. G. R. Laffer, M.P. (Chairman), F. Coleman (Vice-Chairman), Messrs. A. M. Dawkins, C. E. Birks, C. J. Tuckwell, C. J. Valentine, W. J. Colebatch, and G. G. Nicholls (Secretary).

*Mallee Shoot Scorcher.*—Mr. Coleman referred to a proposal previously before the board that the Government should be recommended to offer a bonus for a thoroughly efficient mallee shoot scorcher. After inquiry at the Lamerloo Conference, he felt that such an implement was much needed in the mallee country, and would be a great boon to the settlers. Three manufacturing firms, he had been given to understand, were now engaged in perfecting machines to do the desired work. The chairman stated that he had examined a scorcher in course of construction, and when it was completed the board would be invited to inspect it. Eventually it was decided to defer any definite action until the next meeting, with the idea of arrangements being made for the holding of a field trial of scorchers and other implements early in the new year.

*Fencing Material.*—The secretary reported that the resolution from the Coomandook Branch, suggesting that the Government provide fencing material for boundary fences on newly opened country on the same terms as district councils provide wire netting, had been brought under the notice of the Minister of Agriculture. The reply now received was to the effect that the Advances to Settlers Act provided means of obtaining loans for the purpose indicated or for any other permanent improvements equal to the methods adopted in respect of wire netting.

*Carriage of Perishable Produce.*—Further information respecting facilities for the conveyance of fresh produce direct from producer to consumer, was received from the Agent-General in London. A letter from the Postmaster-General, in London, stated—"There are no arrangements for the special conveyance of perishable goods sent by post, but parcels marked 'Perishable' may be, and to a small extent are, treated exceptionally in certain circumstances. If, for example, there be a long interval between the arrival of parcels and the next ordinary dispatch or delivery, postmasters may, at their discretion, if the circumstances warrant it, make a special dispatch or deliver

such parcels exceptionally, provided they can do so without incurring special expense. In this country parcels frequently travel as rapidly as letters, and often are enclosed in the same receptacles, and are delivered at the same time." From the manager of the Great North-Eastern Railway Company was a letter and a pamphlet relating to the conveyance, at cheap rates, of farm and market produce over the company's lines, and containing a list of the farmers, market gardeners, etc., prepared to forward such produce direct to the consumers. It was pointed out that the charge (including delivery within three miles of Charing Cross and within about one mile of any Great Eastern station in the suburbs of London) was 4d. for parcels up to and including 20lbs. in weight, and 1d. additional for every 5lbs. or part thereof up to 60lbs. The conveyance was at the risk of the owner, and it was provided that the produce should be packed in the boxes on sale at the different stations, or in similar ones, that the carriage should be prepaid, and that no individual box should exceed 60lbs. in weight. It was further mentioned that the number of boxes of produce so carried by this railway company had increased from 173,888 in 1909 to 227,864 in 1913.

*Site for Experimental Farm.*—A communication from the Coorabie Branch (Fowler's Bay) stated that Block 20, in the centre of the hundred of Wookata, 18 miles north-west of Fowler's Bay, would be very suitable for the establishment of an experimental farm. The country was typical of hundreds of thousands of acres of arable land which would be opened up by the suggested railway. It was decided to hand the letter to the Director of Agriculture, who, it was stated, would shortly visit the West Coast.

*New Branch.*—Approval was given to the formation of a branch of the Bureau at Netherton, with the following gentlemen as members:—Messrs. A. Bald, J. Bald, N. A. Brown, J. A. Brown, R. G. Brown, E. R. Byerlee, F. A. Byerlee, L. C. Crouch, T. J. Datson, H. J. Gosden, J. S. Harvey, W. G. Krueger, A. W. Lower, W. R. Peake, S. J. Peake, P. C. Potter, A. C. Ramsay, E. A. Lubecke, C. Mitchell, H. Redman, F. O. Cordis, E. C. Lymn, C. M. Wilkin, J. Donnell, M. P. Wilkin.

*Branch Renamed.*—A resolution from the members of the Albert Branch, to change the name to Glencope, was agreed to.

*New Members.*—The following gentlemen were approved as members of the branches shown:—Appila-Yarrowie—R. Wilson, R. L. Lines; Narridy—J. Liddle; Wepowie—H. W. Noske; Amyton—W. Baumgurtel, A. G. Foulis; Kingston-on-Murray—A. Schencher, W. Farley, jun.; Wynarka—P. N. Collins; Forest Range—H. Moss; Parilla—R. B. Danneey; Canowie Belt—W. Cordon; Narrung—J.

Barker; Strathalbyn—E. E. Brown, J. J. Brown, H. L. Binney, J. Bell, F. G. Grover, J. B. Jackson, E. L. Tucker, E. L. Stirling, E. W. Montgomery, A. Burgess, D. H. McRea, H. H. Butler, J. J. Raggart, C. L. A. Wyatt, J. H. Grinter; Gladstone—A. E. Gale, F. T. Reynolds; Bookpurnong East—S. Hacklin, T. N. Crase, V. Crase, O. Grave; Miltalie—H. W. Lienert; Tarcowie—V. Kotz, E. Muller; Mount Compass—A. Waye; Dowlingville—H. Mason, G. A. Whittaker, L. B. Whittaker, A. Rowntree; Port Broughton—E. H. Allchurch; Tatiara—E. Scott; Freeling—E. Roberts, A. C. Heinjus; Hookina—J. O'Conner, B. Kelly; Northfield—E. Kester; Gumeracha—C. Jamieson; Lameroo—W. Lever, F. H. Mathias, A. Dewhirst, J. Marshall; Port Elliot—S. A. Keen; Mundoorra—E. G. Dolling, R. C. Dolling; Watervale—F. Grace; Coomandook—L. Brown, A. Chapman, J. A. Palm, S. Westgarth, C. E. Lymn, R. Upton, jun.

## REMEDIES FOR WOOLLY APHIS OR AMERICAN BLIGHT.

Mr. A.W. Mack, of Ambleside, who sometime ago had been in communication with the Horticultural Branch of the Department in respect to the treatment of woolly aphis in his apple orchard, has kindly supplied Mr. Quinn with the results of some experiments carried out during the year. He says—"From the results of our sprayings we find that red oil used—one brand made up of 1gall. in 20galls. of water and another brand 1gall. in 25galls. of water—were very satisfactory. We also used crude petroleum, 5galls. to 80galls. of water in which 7lbs. of soft soap had been dissolved; this was also very good. A fourth trial with Burford's kerosine soap, 25lbs. dissolved in boiling water and then diluted to 80galls. of spray, was also tested.

All of these gave about equal results, but of course the great difficulty is found in trying to strike all of the aphides with the spray.

The cost to us of each of the three remedies mentioned is as follows :—

Red oil, 8s. to 9s. 6d. per 80galls. of spray.

Kerosine soap, 7s. 6d. per 80galls. of spray.

Crude petroleum and soft soap, 4s. 6d. per 80galls. of spray.

It should be mentioned that the heavier oils, such as red oil and crude petroleum, are risky to use upon the trees after the buds start in the spring."

## PARAFIELD POULTRY STATION.

## EGG-LAYING COMPETITION, 1914-15.

[Started April 1st, 1914, to terminate March 31st, 1915.]

D. F. LAURIE, Poultry Expert and Lecturer.

## POULTRY NOTES.

**LECTURE AT AGRICULTURAL CONGRESS.**—On the Thursday evening of Congress week a lecture was given in the Brookman Hall, School of Mines, by the Poultry Expert. The subject was "The Egg." A fine series of lantern slides and cinematograph films helped to illustrate the lecture, which was attended by about 400 people.

**VISITS TO PARAFIELD.**—On the Friday of Show week about 70 visitors made the journey to Parafield Poultry Station, and on September 26th, about 130 (including the School of Mines Poultry Class) inspected the incubators, brooders, laying competition, and stock.

**LAYING COMPETITION.**—The weather has been abnormally dry, but the birds are in good health, and egg production is satisfactory. There were 48 cases of broodiness, including three in section No. 3.

D. F. LAURIE, Poultry Expert and Lecturer.

## THE AGRICULTURAL BUREAU.

### THE TWENTY-SIXTH ANNUAL CONGRESS.

#### OPENED BY THE GOVERNOR.

The Twenty-sixth Annual Congress of the Agricultural Bureau of South Australia was held at the Adelaide School of Mines and Industries on Monday, September 7th, Tuesday, September 8th, and Wednesday, September 9th. In many respects the Congress was the most successful yet held. The attendance of delegates averaged 193 at each session.

During the sittings the following delegates attended :—Amyton—W. Gum, A. Wallace ; Appila-Yarrowie—G. S. Wurst, R. L. Lines ; Angaston—E. S. Mathews, W. Patching, S. O. Smith ; Arden Vale and Wyacca—J. H. Williss, O. E. Hannemann ; Arthurton—W. R. Stephenson, S. Welch ; Balaklava—R. S. Goldney, H. M. Tuck ; Beaufort—A. Tard, W. C. G. Underwood ; Beetaloo Valley—A. Bartrum ; Belalie North—I. Gullidge, T. P. Schulz ; Berri—F. R. Arndt, T. L. Hughes ; Blackwood—A. W. Magarey, J. Turner ; Blyth—A. L. McEwin, C. H. Zweck ; Bookpurnong East—R. F. Mayfield, F. M. MacMillan ; Booleroo Centre—W. Michael, N. L. Brooks ; Borrika—V. V. Brown, H. S. Green ; Burra—H. D. Edwards, E. Finch ; Bute—W. H. Sharman, S. Trengrove ; Butler—J. C. Humphreys, R. T. Harrowfield ; Canowie Belt—G. Kirk ; Carrieton—W. G. Brown, J. W. Bock ; Carrow—W. D. Chalmers, W. J. M. Cawley, J.P. ; Cherry Gardens—C. Ricks, G. Hicks ; Clanfield—W. Paull, A. Clutterbuck ; Clare—M. L. Nolan, P. H. Knappstein ; Clarendon—C. S. Spencer, T. B. Brooks ; Claypan Bore—J. Gray, S. Hill ; Colton—E. H. Whitehead, R. Hull ; Coomandook—W. Ninnis, O. Blucher ; Coomooroo—R. G. Polden ; Coonalpyn—E. E. Williams, F. J. Tregenza ; Coonawarra—J. N. McBain, E. F. McBain ; Cressy—G. Lower, J. W. G. Mann ; Crystal Brook—R. R. Shaw, W. W. Robinson ; Davenport—J. E. Lecky, F. Roberts, M. Echert ; Dowlingville—A. J. Phelps ; Elbow Hill—A. Chilman ; Forster—J. Searle, C. Hayman ; Frances—S. Meehan, W. Forster ; Freeling—E. Roberts ; Gawler River—F. Bray, C. Leak ; Georgetown—S. Eyre, J. Buchan ; Geranium—F. Hammond, R. Perrin ; Gladstone—R. E. Lines, J. H. Sargent ; Glencoe—J. Dow, J. J. Halliday ; Green Patch—F. Gore ; Gumeracha—J. B. Randell ; Halidon—J. M. Braithwaite, W. F. D. Clark ; Hartley—J. M. Hudd, J. Stanton ; Inman Valley—

R. Martin, M. J. Meyer; Iron Bank—R. Coats, C. Morgan; Julia—D. S. Heaslip, D. Hombsch; Kadina—J. Malcolm, R. Truscott; Kalangadoo—J. T. Kerin; Kanmantoo—T. Critchley, R. Downing; Keith—A. V. Thompson, J. A. Lock; Kingston-on-Murray—J. Weatherall, J. Aird; Kybybolite—S. Shepherd, E. Leishman; Laneroo—C. R. Eime, S. G. Trowbridge; Laura—E. G. Blesing, R. Lines; Leighton—A. D. McDonald, W. H. Lloyd; Long Flat—J. G. Forster, H. S. Mann; Loxton—L. S. Davie, A. J. Durdin; Lucindale—S. Rayson, H. Langberg; Lyndoch—H. Springbett, G. W. Warren; MacGillivray—H. C. Williams; Mallala—J. A. Arnold, A. H. Marshman; Mangalo—A. G. Burton; Mantung—W. Stewart, G. N. Baker; Meadows—A. L. Ellis, W. Phillips; Meningie—L. D. Martin, W. H. Yates; Milang—M. McBain, W. E. Richards; Millicent—G. Major; Miltalie—J. P. Story; Mitchell—W. Sampson; Monarto South—R. E. Anders, E. Hartmann; Monteith—A. Wells, A. J. Wytkin; Moonta—A. B. Ferguson, W. F. Ortloff; Morchard—W. Toop, H. Kupke; Morgan—R. Wohling, O. Hausler; Morphett Vale—A. C. Pocock, E. E. Hunt, H. V. Sprigg; Mount Barker—H. N. Bell, J. Serymgour; Mount Bryan—A. A. Jeffries, J. Hatherly; Mount Bryan East—J. Thomas, F. Thomas; Mount Compass—W. Cocks; Mount Gambier—R. P. Pritchard, D. A. Collins; Mount Pleasant—H. A. Giles; Mount Remarkable—G. Casley, — Giles; Myponga—M. McGuinness; McNamara Bore—G. H. Parriam, S. Robertson; Nantawarra—J. H. Nicholls; Naracoorte—S. H. Schinckel, J. M. Wray; Narridy—M. Reynolds, P. Haren; Narrung—W. J. L. Thacker, S. Bottrill; North Booborowie—W. B. Ashby, A. V. Simpson; North Bundaleer—H. Stephenson, W. Martin; Northfield—W. J. Dall, J. Williams; Orreroo—J. C. Hagger, W. W. Collins; Parilla—J. J. Foale, G. E. Gregory; Parilla Well—T. Burford, W. H. Foreman; Parrakie—Alf. Dayman, M. Cooney; Paskeville—J. P. Pontifex, R. C. Cowan; Penola—A. H. Strong; Pine Forest—D. Carman, R. D. Goodridge; Pinnaroo—H. Ledger, P. H. Jones; Port Broughton—G. E. Pattingale; Port Elliot—W. Squires, H. B. Welch; Port Germein—J. Stewart; Port Pirie—D. L. McEwin, A. M. Lawrie; Quorn—C. Patten; Redhill—W. M. Hayes, F. A. Wheaton; Renmark—F. Basey; Riverton—F. Phillips, E. A. Gray; Roberts and Verran—F. Masters, D. Hoar; Saddleworth—F. H. Kelly; Salisbury—R. H. Bagster, W. J. McNicol; Salt Creek—H. G. Hornhardt; Sandalwood—W. Willoughby, A. S. M. Lovell; Shannon—M. P. Cronin; Spalding—A. B. Jones, J. J. Gale; Stockport—R. H. Whitelaw, J. Murray; Strathalbyn—P. Cockburn, T. Collett; Sutherlands—J. Badge, A. M. Twartz, jun.; Tarcowie—A. Dempster; Tatiara—M. Sullivan, T. Stanton; Tintinarra—C. P. Hodge; Two Wells—C. E. Oke, W. S. Cordon; Waikerie—J. Parkes, J. J. Odgers; Warcoowie—A. Bairstow, G. Growden; Watervale—J. R. Hamp; Wepowie—F. G. Rooke; Whyte-Yarcoowie—G. McGregor, J. R. Mudge; Wilkawatt—G. A. Oram, M. Neville; Wilmington—A. J. G. Benier, D. S. George; Wirrabara—C. H. Curnow, E. J. Stevens;

Wirrega—R. Williams, L. J. Cook ; Woodside—H. Rollbusch, W. Rollbusch ; Wynarka—R. B. Williams, G. G. Masson ; Yabmana—J. N. McCallum, G. W. Story ; Yadarrie—H. S. Bauer, E. C. Stubing ; Yallunda—T. Forrest, A. V. Teakle ; Yongala Vale—F. Miller, J. Lloyd ; Yorketown—R. Newbold, C. Domaschenz.

### THE OPENING SESSION.

Congress was opened at 8 p.m. on September 7th by His Excellency the Governor (Sir Henry Galway). Mr. G. R. Laffer, M.P. (Chairman of the Advisory Board of Agriculture), presided, and among others present were the Minister of Agriculture (Hon. T. Pascoe, M.L.C.), members and secretary of the Advisory Board, and a large number of officers of the department, including the Director of Agriculture (Professor Perkins) and Mr. W. J. Colebatch, M.R.C.V.S., B.Sc. (Principal Roseworthy College).

The Chairman expressed the appreciation of those present that His Excellency had, he understood, at some personal inconvenience, honored them by his presence. He had much pleasure in asking His Excellency to open the Congress.

### ADDRESS BY THE GOVERNOR.

His Excellency, who was received with hearty applause, said—Your Bureau meets this year under circumstances hitherto unknown in Australia. The greatest war of nations the world has ever seen is now raging—brought about by the Kaiser's accursed system. That monarch held the key to peace or war, and that he and his bombastic advisers chose to force war on the European nations, must ever place an indelible stain on the honor of Germany. The silver lining of this black war cloud is the reply of the self-governing Dominions to the call of the Motherland. The attitude adopted by those Dominions is what was expected ; but it is none the less a grand and lasting proof of the solidarity of the British Empire. Gentlemen, there lies our trump card, and although we may have to face reverses and must endure losses and suffer privations, I feel more than confident that the sacrifices which the British race is now making will result in a glorious conclusion to the present war—not only in saving the Empire, but also in freeing Europe from the accursed despotism which the German Emperor and his satellites are striving to impose upon it. (Applause.)

### COURAGE IN ADVERSITY.

It is difficult to take one's thoughts away from the titanic struggle now going on ; but we have met this evening to talk of other and more healthy things than war and its accompanying horrors. "Agriculture " is the key-

stone of our discourse this evening. On the top of the inconveniences caused by war, and the dislocation of trade which those inconveniences bring about, South Australia has a second very severe burden to bear. I refer, of course, to the drought, the serious nature of which it is probably impossible to calculate. That the visitation of a drought should occur at a time when we can least bear it is indeed a misfortune, and in being called upon to face a double catastrophe, one begins to wonder how the decrees of Providence are ordered. I would suggest, however, that the heavy tax placed upon South Australian farmers to-day is a test of the power of that community to face severe adversity. I am proud in the knowledge that you farmers, though tried very severely, have not been found wanting in that virtue of "heart-courage" which above all will carry you through such a year as this. I had not been many weeks in this country before I learnt that the Australian farmer possessed in no small degree the particular type of courage referred to, and that knowledge, I can assure you, comforted me not a little. We can, too, not unreasonably comfort ourselves in thinking that although this is a year of drought, next year will probably be a year of plenty, and God grant it will be a year of peace, too. (Applause.)

#### AGRICULTURE IN THE MURRAY VALLEY.

It is with no little diffidence that I venture to address this meeting of experts on a subject of which I cannot claim more than a passing acquaintance. I therefore claim your leniency, at the same time expressing the hope that my knowledge in matters agricultural may grow apace during my period of office in South Australia. The position I occupy alone suffices to make me a keen observer of the development of the State's agricultural industries; and in that connection it appears to me that the efforts now being made in the River Murray Valley, and in the locks and other works which are to be constructed on that great waterway, point to an enormous wheat output not many years hence. I read with great interest in the "Weekly Bulletin," not long ago, that should the efforts, now being made, to convert 4,000,000 acres of mallee in the Murray area into wheat lands, prove as successful as has been the case with other mallee lands, South Australia, a decade hence, will export about 7,000,000 bags of wheat annually. These encouraging prospects are brought about owing to the enterprise of South Australian farmers and to their excellent methods of farming.

#### VALUE OF AGRICULTURAL BUREAU.

It is not at all necessary to know anything about agriculture to allow a man of ordinary intelligence to recognise the great good which must necessarily accrue from the amalgamation of ideas, which is the great aim of your Bureau. Looking at the vital importance attaching to the agricultural industry, the founders of this Bureau are to be congratulated and commended on the success which has attended their wise conception. The reading and publica-

tion of papers on the varied agricultural problems is an excellent system; and the value of such literature is greatly enhanced by the arrangement under which all papers can be discussed by the members of your institution, and so allowing that interchange of ideas and experience which cannot but materially assist farmers in solving the many vexed problems which crop up periodically, and enabling them to get the best out of their holdings, whether they be wheat or fruit growers, stock owners, market gardeners, dairy farmers, or poultry breeders.

The manner in which this Bureau works hand in hand with the Department of Agriculture must greatly add to its usefulness, and whilst congratulating you on your large membership and on the work you have thus far accomplished, I would express the hope that the number of your members may increase in proportion to the importance of the laudable objects which you have in view.

It is plain, too, that the value of your Bureau is not confined to its economic uses. There is a very happy social aspect as well. The many meetings held by the Bureau and by its numerous branches throughout the State allow farmers to get to know each other better, so leading to that spirit of camaraderie which obviously must tend to enhance the success of the undertaking, whose watchwords are Progress and Co-operation. I think the Agricultural Bureau can fairly be termed the farmers' *vade mecum*, or to put it in English the "Farmers' Manual." May the time come, and soon, when the membership of the Bureau and its branches will form a complete list of the producers of the State.

In conclusion, I would express the hope that the work of the Bureau may continue to progress, and that the brave spirit in which the farmers of this country face adversity may receive its due reward. (Applause.)

### THE MINISTER'S SPEECH.

The Minister of Agriculture (Hon. T. Pascoe, M.L.C.), who was warmly applauded, said—

I am sure it has been very inspiring to all of us to have listened to the fine address His Excellency has delivered. We are glad, indeed, that His Excellency has followed the example of his predecessor in attending to open our annual Congress. I happen to know that there were two engagements which His Excellency was asked to fulfil to-night, and though one of those might have proved more interesting to him personally than this gathering, he kindly put them both aside in order that he might be with us, the agriculturists of South Australia.

### THE DROUGHT.

His Excellency has referred to the troubles which have come upon our nation owing to the war. Personally, I do not think that at this fringe of the great British Empire, if the war alone had come, we would have suffered

overmuch ; but, unfortunately, the war has come at a most inopportune time. In addition to the war, South Australia is passing through a period of unprecedented drought. The weather in Adelaide during August put up several records. The rainfall was less than half the previous lowest on record, in addition to which the month was the warmest, and the consequent evaporation also the greatest on record. The rainfall for the eight months throughout the greater part of this State is, this year, the lowest on record. A few instances may be quoted as showing the extreme conditions—At Hawker the average rainfall to the end of August is 8·58in., this year it has been only 2·42in. ; at Terowie the average to end of August is 9·12in., this year it is 3·21in. ; at Jamestown (one of our most reliable districts) the average is 11·71in., this year it is 4·36in. ; at Crystal Brook the average is 10·88in., this year it is 5·21in. ; at Snowtown the average is 11·30in., this year it is 4·69 inches ; at Cowell the average to end August is 8·33in., this year it is 5·19in. ; at Fowler's Bay the average is 9·54in., this year it is 4·13in. ; at Gawler the average is 13·63in., this year it is 9·01in. ; at Adelaide the average is 15·19in., this year it is 8·00in. ; at Eudunda the average is 12·09in., this year it is 5·38in. ; at Minlaton the average is 12·95in., this year it is 8·75in. ; at Lameroo the average is 10·88in., this year it is 5·59in. ; and at Penola the average is 18·71in., this year it is 9·71in.

#### HELP FOR DROUGHT-STRICKEN FARMERS.

Those are representative places scattered throughout the State, and the figures I have quoted show the severity of the drought. The result is that the year has not been a bed of roses for the Department of Agriculture. It has fallen to our lot to give assistance to drought-stricken farmers in the North, and we have shifted from that part to slightly better favored districts in the South about 1,200 cows. When we started to shift these cattle we did not expect that it would be necessary to make provision for them for so long as now appears probable. To meet possibilities, however, and at the same time to provide a reserve of hay to meet possible demands for next year's seeding operations, the department is putting nearly 1,000 acres under lucerne and millet. In this connection I wish to express our indebtedness to the southern settlers who came to our help by providing cheap grazing for the northern stock. (Applause.)

#### IRRIGATION AND RECLAIMED LANDS.

In a season like the present more attention is directed to the value of irrigation, as owners of irrigated land are to a very large extent independent of the season. Probably no finer object lesson in closer settlement in Australia can be found than on our reclaimed swamp lands on the Murray. On the Monteith Swamp, for example, which has been reclaimed and settled by the Government, there are 37 settlers, and a total population of 153

persons. On June 30th 345 acres were under lucerne, and 290 under other crops, while the area carried 776 cows, 500 sheep, and 135 horses. This, too, in the middle of winter, when the fodder supply is practically at its lowest. (Applause.) The total area of the settlement is 1,920 acres, of which 986 acres are swamp land. Within the next two years the balance of Mypolonga Swamp and the swamps known as Jervois, Swanport, Wall, and Pompoota, approximately 4,075 acres, will be settled, and there is no doubt that in the future the 40,000 acres covered by the waters of Lake Albert, if not even the larger area of Lake Alexandrina, will be drained and settled. My private opinion is that it is to the valley of the River Murray that South Australia must look for any great increase in her producing population. We have nearly reached the end of our development as regards safe agricultural land, but there are great possibilities in the Murray Valley for closer settlement, and it will eventually carry a very large population. (Applause.)

#### DEPARTMENTAL STAFF CHANGES.

It is but fitting I should make some reference to the changes in the department brought about by the resignation of Professor Lowrie as Director. Fortunately we possess a staff of such competent officers that it was not necessary to go outside the department in making the necessary reorganisation. In Professor Perkins (the present Director) we have probably the ablest agricultural authority in Australia. Unquestionably the experimental work carried out by him at Roseworthy during the past 10 years has no parallel in the Commonwealth. (Applause.) The Government naturally were reluctant to move a man filling his position so ably, but believed that, in his wider sphere of work as Director, Professor Perkins will be equally successful, especially as he will have the assistance of Mr. Spafford, who has been associated with him for many years in the experimental work at Roseworthy. These two gentlemen will not only give effect to the Government policy to extend the scope of experimental work throughout the State, but will give a much closer supervision to the work than has previously been the case in the past. This has undoubtedly been one of the weak points of our work. Tomorrow evening Professor Perkins is to review some of the work done at the College during his term of office as Principal. Though appropriate to the occasion, he has undoubtedly set himself a task of great magnitude. I have no doubt that the address will prove one of the most important we have had at any Congress meeting. Mr. Colebatch, the new Principal of the Roseworthy College, possesses the confidence of the Government, and we believe he will prove a worthy successor to Professor Perkins. You know how highly we appreciate the abilities of Mr. Colebatch, and in regard to his appointment, I believe that it is the first time in the history of Australia that a former student of a college has risen to be its Principal.

## THE SOUTH-EAST.

In the South-East we have during the last two or three years had favorable seasons, but, unfortunately, what is a favorable season there is very often unfavorable in the North. Relatively dry seasons have during the past two or three years been experienced in the South-East. At Kybybolite the rainfall last year was 18.44in. The settlers in the South-East are following the lead given in drainage of soils, and are securing the use of special implements (crowder) for constructing channels for drainage. Mr. Colebatch considers that of all the problems confronting settlers in that district that of drainage is of paramount importance. Before long he thinks the settlers will regard the channelling of their cropped areas as essential as bare fallowing. He is much impressed with the possibilities of the Kybybolite country if properly farmed. Experiments on farmers' plots have been continued, and this work, together with the experimental work at the Kybybolite Farm, will be continued under the control of the Director, assisted by the Superintendent of Experimental Work (Mr. Spafford).

## VISIT TO ROSEWORTHY.

I am sorry that we cannot arrange for a visit to Roseworthy College this year. Last year the visit, owing to the dry season, was, from an educational point of view, almost a total failure. This year the conditions are but little better, and the Government feel that under present financial conditions it would be better to utilise the money which that outing would cost in some other way useful to the agriculturist. (Applause.)

## HORTICULTURE.

The work of the various sections of the department is progressing satisfactorily. In addition to the general work of the Horticultural Department, the staff under Mr. Quinn is now initiating testing operations in respect to seeds imported for commercial use, and it is hoped that, as a result, the public will in time be supplied with higher quality seeds in respect to purity and germination than is sometimes the case at present. It is interesting to note that our senior Fruit Inspector is the Commanding Officer of the South Australian mounted unit of the expeditionary force which leaves for Europe in a few days. I refer to Lieutenant-Colonel Rowell. Another officer, Lieutenant-Colonel Miell, as well as several of the men, are members of the Bureau, and I am sure our best wishes go with them. (Applause.)

## THE POULTRY FARM.

The Poultry Expert has now got Parafield in good working order, and those interested in poultry-breeding will be afforded the opportunity of seeing what is being done there. Of special interest is the mammoth incubator, with a capacity for 5,000 eggs. I am glad to say that a considerable amount

of capital is being put into large commercial poultry plants, and the services of the Poultry Expert and his staff are in demand for assistance in preparing plans, &c.

#### VETERINARY LECTURES.

The Veterinary Lecturer (Mr. Place) has given a full course of four lectures to 25 Branches of the Agricultural Bureau, which have also received practical demonstrations. On 20 occasions he has made special visits for the purpose of giving advice. The total number of cases upon which he has advised is 1,237, of which he has personally seen 1,080. He has delivered 155 lectures and carried out 114 demonstrations, including 60 *post mortems*. In the performance of these duties he has travelled 17,132 miles. There is much keener interest in the veterinary subjects taught by him at Roseworthy Agricultural College, and the fact that farmers near there are willing to bring patients to the College for advice, thereby enabling the students to obtain first hand acquaintance with diseases which otherwise they would not likely be able to see while at the College, is gratifying.

#### THE DAIRY INDUSTRY.

This season has given the dairy industry a serious set-back from which it will take several years to recover. The Dairy Expert and his assistant, Mr. Apps, have had a trying time during the past few months in connection with the removal of starving stock from the North, and I wish to record my appreciation of their work in this connection. Next season we hope to be able to make a start (under the supervision of Mr. Suter) on a scheme for the systematic testing of the milking qualities of our dairy herds.

#### FUNGUS DISEASES.

Since Professor Osborn's appointment as Professor of Botany at the Adelaide University he has acted as Consulting Botanist and Pathologist to the Agricultural Department. Professor Osborn has given a good deal of attention to the numerous specimens of plants submitted <sup>the</sup> chiefly by members of the Agricultural Bureau for identification. He has had occasion to remark on the rapidity with which many useless plants spread in the newly-settled areas, a fact which emphasises the importance of clean seed for sowing. The Professor's attention has also been given to various inquiries concerning fungus pests, and he would welcome specimens of plants affected by diseases of this character. He has given considerable attention to the ravages of takeall, and calls attention to two important facts, one being that the fungus can live in an air-dried condition for at least 18 months, so that it may be carried from one paddock to another after the affected plants have been dead for a long while; and secondly, that he has discovered it on oats, which, though only slightly affected, is disappointing, in view of our previous experience of the benefit derived from cropping takeall affected land with oats.

## TESTING WATER SUPPLIES.

Another matter to which the department has been paying a good deal of attention is the testing of the quality of our water supplies, both for stock and irrigation purposes. Unfortunately, we have very little reliable data to guide us in respect to either aspects of the question, and this can only be obtained by a series of tests over a number of years.

## BULK HANDLING OF WHEAT.

The Government have been taken to task in some quarters for not having given effect to a previous resolution in favor of bulk handling of wheat. A resolution of Congress in 1913 was—"That this Congress urge the Government to take such steps as may be necessary to make bulk handling of wheat the ordinary process of marketing in this State." If we can believe some of the so-called authorities on the subject, there are no real difficulties in the way, and an expenditure by the State of £250,000 would save the farmers—well, the figure has been variously estimated at from £50,000 to £100,000 per annum, and one authority, in his anxiety to further the farmers' interests, says of course they would not be expected to pay interest on the capital outlay. I differ from this gentleman, because I do not think our farmers want to dodge paying interest on the cost of works for their benefit, and if they did they would certainly be disappointed. The farmers can rest assured that we are not neglecting our duty in this matter. The farther we go into it the more doubtful we are whether, under South Australian conditions, the system will prove profitable. It may be that the scheme will prove practicable so far as the areas commanded by Ports Adelaide, Wallaroo, and Pirie, but even this will depend upon several factors. We do not know whether bulk wheat, after cleaning, will command proportionately higher prices than the present f.a.q. bagged wheat. We are told that in every bushel of wheat shipped to Europe we pay freight and charges on 3lbs. of waste, or, say, 5 per cent. This represents an unnecessary expenditure on freight, &c., of approximately 50s. per 1,000bush. If we can obtain the benefit of this saving it would practically settle the financial aspect, but the evidence we have renders it very doubtful.

It may interest you to have some idea of the difficulties we would have to face in erecting elevators at the three ports mentioned. The question of foundations is of the utmost importance to the stability of these structures, and the total cost of elevator and equipment is largely dependent upon the nature of the ground. Reports we have in the department show an enormous variation in the costs of the different elevators—from as low as £50,000 to as high as £150,000 per million-bushel capacity. In the construction of the large elevator for the Grand Trunk Pacific Railway at Fort William, Ontario, 12,000 60ft. piles were used on which to build the concrete foundation, while over 60,000 cubic yards of concrete and 2,500 tons of steel reinforcing bars

were used in the erection of the buildings. This was for an elevator to hold three and a half million bushels. At the Outer Harbor we would have to put our foundations on piles of an average length of 57ft. to get solid bottom to carry the weight, and the silos and plant for a million-bushel elevator would probably require 3,000 or more of these piles—a very costly start. At Port Pirie the same conditions exist, except that 45ft. piles would be required; while at Wallaroo we are faced with the problem that we would have to load vessels at a jetty 2,830ft. in length.

Because Congress passed a resolution last year in favor of bulk handling of wheat, without having any idea of what the adoption of that system would cost, some people thought the Government was bound to carry out that resolution. All I read in that resolution was that you desired full inquiries should be made so that it could be ascertained if any alteration in the present system would be of benefit to South Australia. You can rest assured that while the present Government is in power they are not going to rush into an alteration of the whole system of wheat marketing and force the producers to bear the cost unless they can see that the producers will receive some benefit from the change. (Applause.) I desire to express my appreciation that such a large number of delegates have in these trying times attended this Congress. Your presence speaks well for your courage and enthusiasm, and I sincerely hope you all will have a pleasant and profitable time. (Applause.)

#### THE CHAIRMAN'S ADDRESS.

The Chairman of the Advisory Board of Agriculture (Mr. G. R. Laffer, M.P.) addressed the gathering and detailed some of the work which had been accomplished by the Advisory Board and the Agricultural Bureau during the year just passed. He said—Members of the Bureau will be interested to hear of the work of the Board during the past 12 months. A multitude of matters of minor importance has been dealt with, and it will only be possible now to speak of some of the more important.

#### IMPORT DUTY ON SUPERPHOSPHATE.

The first I will mention is that of the proposal to impose a duty on imported superphosphates. Immediately this was mooted, with the approval of the Minister, forms were circulated through every Branch of the Bureau for a petition against the imposition of this duty on the grounds that it was quite unnecessary for the protection of the local industry, and that it would tend to restrict the application of this essential manure on the wheat lands of our State. Over 3,000 farmers and other producers signed this petition, which is being held over for presentation to the inter-State Commission if or when the occasion arises. The Board also appointed two of its members, Mr. F. Coleman (vice-chairman) and Mr. A. M. Dawkins (an ex-chairman), both practical farmers, to give evidence before the inter-State Commission when the members sit in Adelaide.

## VETERINARY LECTURES.

I know that very many of you gentlemen have appreciated thoroughly the lectures, demonstrations, and the advice given by the Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.). The Board has used its influence to bring about the production in pamphlet form of copies of Mr. Place's addresses, and although they will not be produced in just the same form as that in which they are delivered at the Branches of the Bureau, you will be glad to know that arrangements are being made for a bulletin or farmers' handbook, from the pen of Mr. Place, to be published a little later on. (Applause.)

## AFFORESTATION.

As members of the Bureau are aware, the Advisory Board has always advocated afforestation and the preservation of natural timbers by both the State and the individual landholder. Earlier in the year all the Branches in the Pinnaroo district were asked to consider the matter of the provision of windbreaks and stock shelters throughout the newly-settled mallee lands, and to send their delegates to the local Conference prepared to deal with the subjects. At the request of the Board the Conservator of Forests (Mr. W. Gill, F.L.S., F.R.H.S.) courteously attended and offered very practical advice at the Conference which was held last month at Lamerloo. As the result of this and the interesting discussion which took place, settlers in that part of the State will have some valuable information to guide them in the handling of their properties in this regard.

## SALINITY OF STOCK WATER.

On every possible occasion the Board has endeavored to assist the department in its work of investigation, thus reciprocating the very material assistance which the Bureau derives from the officers of the department. As an instance of this, during the past year arrangements have been made for samples of saline stock waters to be forwarded at regular intervals to the Agricultural College to be analysed. By this means the Director hopes in time to be able to present reliable data in respect to the degrees of salineness in water that can be tolerated by stock. The Board highly appreciates the co-operation of those Branches of the Bureau that are regularly sending samples.

## MARKET FOR BARLEY.

As Chairman of the Board it was my privilege to ask that inquiries should be made in England as to the existence of markets for barley. A full report of the result has been published, and I will now only say that it was ascertained that barley similar to the samples forwarded would probably command prices ranging from 3s. 3d. per bushel for the inferior to 4s. 9d. per bushel for the best sample sent. It is hoped that this preliminary information will be of value, and may possibly lead later on to some trial shipments in those seasons when local prices are low.

### THE AGRICULTURAL BUREAU.

As you know, most of the duties of the Board are in connection with the work of the Agricultural Bureau. You will be glad to learn that the extension of the work of this institution has been steadily maintained during the past year. For the year ended June 30th last 12 new Branches were opened, and two were closed through lack of interest, leaving a total of 163. Since then seven additional Branches have been formed, making a total of 170 at the present date. The membership of the Branches rose last year from 3,400 to 4,000.

The rule in regard to retirement of those who have not attended regularly has been enforced with reasonable stringency, for it is the aim of the Board to have effective Branches consisting of active members whose work is not hampered by a number of men whose interest is only aroused by annual meetings or a social. As an indication of the increased popularity of the Bureau, and of the thorough manner in which rolls have been purged, I may say that the average number of members per Branch has steadily risen as follows during the past eight years :—For the year ended June 30th, 1906, the average number of members per Branch was 16 ; at the same date in 1910 the average was 20 ; 1911, 21 ; 1913, 22 ; and 1914, the average number was 24·5. (Applause.)

### LIFE MEMBERS.

During the year the distinction of life membership has been conferred upon 46 gentlemen, making a total number of life members at the present date of 108.

### COUNTRY CONFERENCES.

Members of the Board have attended all the Country Conferences. There has always been one representative, and sometimes as many as three ; and a matter which has given members great satisfaction has been the regular attendance of the Honorable the Minister at these gatherings. The Hon. T. Pascoe, M.L.C., has only missed one of the seven Conferences that have been held, and that one was held on Eyre's Peninsula at a time of the year when Parliamentary duties made it impossible for him to leave the city for the length of time involved.

### EXPERIMENTAL DEMONSTRATION PLOTS.

The need for more practical work among the Branches of the Bureau was brought under the notice of last Congress in an address by the Secretary (Mr. G. G. Nicholls), who suggested briefly lines of work suitable for the Branches to undertake. After discussion, a resolution was unanimously carried in favor of the proposals made, and a committee, whose members were representative of the various sections of agriculture and of the districts north, south, east, and west, was appointed to deal with the matter. The committee prepared suggestions for lines of work for the Branches, and these

were duly communicated to all the hon. secretaries. The response has been most encouraging, over 50 Branches having signified their intention to lay down plots this year. Probably many of these will have no returns to present after harvest owing to the unprecedentedly dry season which is now being experienced ; but it is satisfactory to know that very many of the Branches realise that they can vastly improve the value of their work by conducting some of these practical tests, and that given more favorable seasons much valuable information will be gained. Provision is made for the appointment of a committee of supervision in each Branch, so that accuracy—for the practical purposes of a farm demonstration plot—can be vouched for when returns were presented.

#### VISITS TO BRANCHES.

In the earlier history of the Bureau, members of the Central Bureau made a special feature of visiting as many Branches as practicable. This custom has been revived during the past year to a certain extent. The Chairman visited the River Murray Branches and Southern Branches ; other members the Strathalbyn, Stockport, Riverton, and Mount Bryan ; Secretary the Parilla, Clare, Freeling, Morgan, Parilla Well, Geranium, Mount Bryan, Laura, Mount Compass, Clarendon and Murray River Branches, and Hartley ; and Mr. H. J. Finnis Coonalpyn, Hallidon, and a number of the other newly-formed Branches on the Tailm Bend to Loxton and Paringa Railways. There is no doubt that it is advisable for an officer to attend the opening meetings of new Branches to suggest ways of working, and the Board has asked the Secretary to do this as often as practicable, and to visit as many of the Branches as he can.

#### THE PRESS.

I desire to acknowledge the great indebtedness of the Agricultural Bureau to the South Australian Press. The Adelaide papers invariably give full reports of the deliberations of the Board. By sending their representatives to the Country Conferences and to the Annual Congress they give an impetus to the work of the Bureau, and at the same time convey to the man upon the land a great deal of information which is of practical worth. The country papers also assist the work of the local Branches, and by reprinting papers read at the meetings, give much wider publicity to the views of experienced men regarding many agricultural problems. (Applause.)

#### VOTE OF THANKS.

Mr. F. Coleman (Advisory Board) proposed a vote of thanks to His Excellency for presiding. His Excellency had referred to the drought. No doubt the position was serious, but South Australian farmers had a reputation for rising superior to circumstances. (Applause.)

Mr. A. M. Dawkins (Advisory Board) seconded the motion. He was sure they had all been inspired by the fine address of His Excellency. He could

assure Sir Henry Galway that there were no more loyal body of citizens than the farmers. (Applause.) With regard to the drought, they had experienced bad times before, and knew that good times would come again.

The motion was carried by acclamation.

#### THE GOVERNOR'S REPLY.

His Excellency in reply said his address had been described as very excellent. It was all kindness which prompted that eulogy. He did not look upon it as an address at all. The idea of his standing up there and talking to them about agriculture was nonsense. He did not know anything about it, but he hoped to some day. One did not come to Australia, however, without hoping to learn something, especially regarding agriculture and farming generally. If a member of the audience stood up there before a gathering of soldiers and gave them an address on strategy and tactics it might appear well on paper, but the soldiers probably would not think very much of it. It was very kind of them to receive him as they had. He saw that the great prosperity of Australia, and of South Australia particularly, lay in the land, and therefore it was only natural that he should be a very willing pupil. Whether he was a particularly clever one remained to be seen. But every year he had the honor of presiding at that Annual Conference, as he hoped he would have, he trusted that he would prove to be more interesting than he had been that evening. In conclusion, he sincerely hoped they would always be as lenient as they had been on that occasion, and if they were he would then get on very much better.

The Congress then adjourned till the following morning.

#### TUESDAY, SEPTEMBER 8th.

##### MORNING SESSION.

Congress resumed its sittings at 9-30 a.m. on Tuesday, September 8th. Mr. Coleman (Vice-Chairman Advisory Board) presided.

#### EXPERIMENTAL AND DEMONSTRATION PLOTS.

At the closing session of the 1913 Congress the following were appointed a committee to formulate plans and suggestions for the establishment and working by members of the Bureau of experimental and demonstration plots:—Northern Districts—W. Gum, Amyton; S. Eyre, Georgetown. Lower North—J. P. Pontifex, Paskeville; E. A. Gray, Riverton. Hills and Fruitgrowing—C. Ricks, Cherry Gardens; S. O. Smith, Angaston. Irrigation Areas—H. S. Taylor, Renmark; F. G. Rogers, Waikerie. East of Murray—

W. B. Russell, Loxton ; A. J. A. Koch, Lameroo. South and South-East—S. H. Schinckel, Naracoorte ; C. P. Hodge, Tintinara. Eyre Peninsula—F. Masters, Roberts and Verran ; E. M. Sage, Green Patch.

Mr. S. Osborne Smith (Chairman) submitted the report of the committee as follows :—" The committee met on the day of their appointment and prepared an outline of work suitable for Branches of the Bureau to undertake. It was decided to suggest that each Branch should select one or more of the following subjects for demonstration :—

*Wheat-growing Areas.*—(1) Methods of cultivation ; (2) Wheat—(a) Varieties, (b) Quantities of seed ; (3) Manures—(a) Quantities, (b) Kinds.

*Fruit and Irrigation Areas.*—(1) Manures—(a) Various manures for different kinds of fruit, (b) Times to apply certain manures, (c) Relative advantages of top and deep applications ; (2) Pruning of deciduous trees.

*South-Eastern Area.*—(1) Potatoes—(a) Seed, (b) Manures, &c.

*General.*—(1) Fodders (especially in wetter districts) ; (2) Improvement of pastures ; (3) Soil improvement by the application of lime (especially in the wetter districts).

These recommendations were forwarded to all Branches of the Bureau early in November, together with a report of the Secretary's introductory remarks to the Congress. At the same time suggestions were made to the Branches in the following terms :—(1) Secure offers to conduct the plots from one or more members ; (2) Appoint a local committee of, say, three, whose duties would be—(a) To select the land as nearly uniform as possible for each plot in a given test. (b) Check the measurements of plots, weights of seeds, manures, &c., as well as weight of produce after harvest, and generally supervise at seed time and harvest, as they may consider necessary to ensure the accuracy of the work and reliability of the results. This is of importance if the results are to be accepted as trustworthy by others, and that is a great consideration. (c) Prepare a report after harvest from records kept by one of the committeemen. To sign same and present to the Branch for discussion and transmission for publication. In large Branches more than one committee could be appointed to duplicate the tests or widen the scope of same. (3) Advise the Secretary not later than the end of the year whether your Branch intends to take any action in the direction indicated.

As only a few replies to this communication had been received by the end of the year, a further circular was sent to each Branch in March. The response to this has been very gratifying, and your committee feels justified in reporting that there is every prospect in normal years of valuable work being done. Sixty Branches have indicated their decision to undertake such work this year. Of these, 45 have advised us of the names of the local committeemen appointed to supervise ; 33 have indicated the nature of the experiments to be undertaken ; and 30 have furnished the names of the members on whose farms, and by whom, the work is to be done.

Complete returns, giving names of committeemen, nature of work, and names of demonstrators have been received from 20 of the 60 Branches. We have said that 33 Branches have indicated the nature of the work undertaken. This work may be summarised as follows :—

|                                              |    |          |
|----------------------------------------------|----|----------|
| Tests with various quantities of super. .... | 19 | Branches |
| “ high and low grade super. ....             | 1  | “        |
| “ potassic manures ....                      | 2  | “        |
| “ “Beatsall” ....                            | 4  | “        |
| “ manures for fruit and vines ....           | 4  | “        |
| “ varieties of wheat ....                    | 21 | “        |
| “ seed per acre (wheat) ....                 | 4  | “        |
| “ methods and depth of cultivation ....      | 2  | “        |
| “ grasses and fodders ....                   | 1  | “        |
| “ potatoes ....                              | 1  | “        |
| “ onions ....                                | 1  | “        |
| “ mangolds ....                              | 1  | “        |
| “ lime ....                                  | 1  | “        |
| “ peanuts as an irrigation crop ....         | 1  | “        |

Many of these Branches have indicated more than one of the above-mentioned subjects, and in some of the tests as many as eight plots are laid down. Of the 33 Branches referred to, 16 are in the newly-settled mallee country east of the Murray River, on Eyre's Peninsula, and on the West Coast.

The members of your committee do not expect in such a season as this that returns of harvest results will be forthcoming from the whole of the Branches, which earlier in the year advised us as herein reported. We do, however, consider that a good start has been made, and that as time goes on reports will be received of valuable demonstration work achieved.

It is proposed to classify as “Experimental work” the results of those tests which can be expressed in exact terms of measurement, &c., and as “Demonstration work” those which cannot be expressed in exact terms, *e.g.*, fruits, pastures, &c.

In conclusion your committee recommends that a report such as this be presented to the Congress each year, at the first business session. S. OSBORNE SMITH (chairman) GEO. G. NICHOLLS (secretary).”

#### REPORT ADOPTED.

In moving the adoption of the report, Mr. Smith said he was glad to say that the committee had the hearty co-operation of the Director of Agriculture and his staff. Farmers could not all be scientists, but the committee included a number of old Roseworthy College students, and it was largely from them they expected good results as regarded the experiments. One result of the ex-

perimental work would be to stimulate enthusiasm among the members of the Bureau, and the value of the experiments would increase as the years went on. (Applause.)

Mr. E. J. Pearce (Whyte-Yarcowie) seconded the motion for the adoption of the report.

Mr. P. Cockburn (Strathalbyn) said undoubtedly if the farmers were going to progress in the practice of agriculture they could not do better than carry out experiments. He thought the suggestions of the committee were commendable. He cordially supported the adoption of the report.

Mr. A. Bairstow (Warcowie) thought Bureau members could not do better than carry out the suggestions contained in the report. In his district certain experiments had been tried this year, but owing to the dry season no results had been achieved.

Mr. J. N. McCallum (Yabmana) considered the report of the committee would commend itself to those present as farmers and members of the Bureau. His Branch was fully alive to the importance of carrying out the suggestions made.

Mr. J. Malcolm (Kadina) said that in common with other Branches his branch had taken up the work. Even if the results were very poor this season they would at least show what could be done in an unfavorable year. He supported the proposals of the committee most heartily, but hoped that individual experiments would also be continued.

The motion was carried unanimously.

#### ELECTION OF COMMITTEE.

Mr. P. H. Jones (Pinnaroo) moved—"That the members of the experimental committee appointed last year be re-elected; that the committee be given power to fill any vacancies which may occur; and that the experimental committee be elected annually at Congress."

Mr. A. A. Jeffries (Mount Bryan) seconded the motion, which was carried unanimously.

#### WHEAT-GROWING DEMONSTRATION PLOTS.

Mr. E. J. Pearce (Whyte-Yarcowie) read the following paper:—

At the outset it will be agreed that among the many reasons for advocating experimental or demonstration work for the Bureau, is the fact that soil and climatic conditions vary very greatly in different parts of the extensive agricultural areas of this State. In my own district; for example, soils vary from a light loam, with a limestone rubble subsoil, to a heavy loam with a strong, almost impervious, clay subsoil. It is evident to the merest novice that the same methods of cultivation are not suitable to these distinctive soils. The object of this paper is to give an outline of what in my opinion is the

best method of conducting such demonstration plots as may be thought necessary, having regard to the conditions obtaining on the average farm ; and so conducted that whilst not laying claim to scientific exactness, would be accepted as approximately correct, and reliable as a guide in the general practice of farmers whose conditions were similar. There are three main lines on which we can experiment, viz. (1) methods of cultivation, (2) manures and manuring, and (3) varieties of seed, including selection and preparation of the same.

#### THE CULTIVATION OF THE SOIL.

In the case of deep v. shallow ploughing, if the test to be made is very deep, say 10in. v. 4in., it would be necessary to permanently mark the plots in order to watch the effect over a series of years. I adopted this plan : Cut out some small squares of galvanized iron and numbered them from I. upwards with Roman numerals, these being easily cut out. These were then nailed to jarrah pegs, which were driven into the ground at one end of the plots. At the other end there being a fence, similar duplicate plates were attached securely to the fence. The advantage of these permanent marks in an experiment of this kind is that all operations except the ploughing can be done either way ; and such a very deep ploughing as 10in. would show an effect for many years, the subsequent working of the land, excepting for harvesting, might be done without regard to the limits of the plots. Then at harvest time it would only be necessary to define the plots by cutting tracks from peg to peg, and the plots could be harvested separately as long as it was thought desirable to continue the experiment. The numbers, with particulars of what they represent, to be entered in a book kept for the purpose of a record of experimental work and results.

This permanent marking is necessary, and only necessary when results are likely to be seen over a series of years, such as an experiment with heavy dressings of farmyard manure or lime, and when a test of bare fallow and wheat v. a rotation of crops, &c., is desired.

In experiments where the result is to be noted for the one crop only, such as grades and quantities of super., quantities of seed per acre, grading of seed, etc., it will be sufficient to define the boundaries of the plots by leaving a margin of 14in. between each. This is easily accomplished by driving the wheel of the drill on the last wheel track instead of on the hoe mark.

#### MANURIAL PLOTS.

In making a test of heavy v. light dressings of super. it is of course necessary to use the same brand of super., and also the same variety and quantity of seed throughout. To test the relative value of dressings of  $\frac{1}{2}$ cwt., 1cwt., and  $1\frac{1}{2}$ cwts. of 36-38 per cent. super., I would first select a piece of land as nearly as possible uniform in quality, and which in fallowing and subsequent working had been treated all alike. Then I would take one variety of seed, and would

set the grain feed of the drill to sow the desired quantity per acre, say, 1bush., and leave it at that for the whole of the plots included in the test. I would then weigh and mark, say, four bags of super., and set the drill to sow as nearly as possible 56lbs., and proceed to sow plot No. 1, leaving the manure feed as set. On the completion of that plot, remove all the super. from the drill and return to the bag from which it was taken, to be weighed; then enter in the book as follows:—"Experimental plots—quantities of super. All plots numbered from east to west (or as the case may be). Plot No. 1—Adelaide Chemical Works super., 36-38 per cent., 56lbs. per acre. Federation seed, 1bush. Area of plot, 2 acres. Sown May 15th, 1914."

Your drill may not have put on the exact quantity you desired, perhaps only 54lbs., or may be 58lbs. This is immaterial. Just enter the exact quantity used. Then proceed with plots 2 (1cwt.) and 3 (1½cwts.) in the same way, making the only difference in the quantity of super, and being extremely careful to enter everything in the book exactly as done. It is not necessary to be particularly careful as to the exact area of the plots when sowing. I find it more convenient to rely on the drill surveyor as a guide to estimate the quantities by, and then take so many sweeps of the drill according to the length of the piece of land you are operating on. Supposing the drill registers an acre in a round, and I wish to sow a four-acre plot, I would go four rounds. It is always advisable to sow one plot in any series of manure tests without any manure as a check, and to show what you are gaining by the manure used.

This season I have put in 13 plots on the above system, each containing about two and a half acres, being three rounds with a 17 x 7 drill. They are defined by a 14in. space between each. At hay time I will cut a 12ft. track with the binder between each, that will leave the plots about two acres each, but at harvest time I will put the chain on and calculate the exact area.

#### SEED TESTS.

If your experiment is to decide the most profitable quantity of seed to sow per acre the same procedure should be followed as above, with these differences: You will use the same kind and quantity of manure on each plot, and the same variety of seed, varying the quantity only. If you are testing varieties of wheat, sow the same quantities of manure and seed, the difference being in variety of seed only.

If you wish to test the benefit of graded over ungraded seed, the only difference should be in the matter of grading.

#### SIZE OF PLOTS.

I think a two or three acre plot large enough. If you make them larger there is a difficulty in getting land even in quality. If they are smaller

there is greater danger of error in computing the results, as obviously a few yards difference in area or a few pounds difference in product will cause a greater discrepancy on a quarter-acre than on a two-acre plot.

#### SEPARATE HARVESTING OF PLOTS.

This is one of the most important points in the conduct of experiments. I have heard members at Branch meetings remark, "I tried one piece with a dressing of 60lbs. of super., and another alongside with 80lbs., and I could not see any difference," or "I graded all my seed, and I am satisfied I got 2bush. more to the acre than my neighbor who did not grade." As a matter of fact it is impossible to judge a crop by the eye. Take a 20bush. crop and one that will yield 25bush. standing side by side. There is a difference of 25 per cent., yet I question if the most experienced could detect it. In 1909 I conducted some experiments for the department. There were four plots, three were manured with 100lbs. of super. and upwards, and the fourth was drilled in without manure. Throughout the season there appeared to be little to choose between the manured and unmanured plots. I thought at all events the unmanured would be the most payable, having regard to the cost of super. When the plots were harvested, however, and the product weighed, there was a difference of 3bush. 18lbs. per acre, leaving a profit of 9s. 3d. per acre in favor of the most heavily manured plot. It is not a difficult matter to harvest separately with the complete harvester, nor is there so much lost time as some would suppose. It is unnecessary to clean out every grain in these tests if the machine is run a few chains after finishing each plot to clear the elevator cups, and just a little extra care is taken in cleaning out the box, you have, for all practical purposes a correct result. Any discrepancy there may be is negligible when spread over two acres.

It is necessary of course that the produce (grain) from each plot should be kept separate and weighed, and the result entered up in the book as early as possible. It is desirable, if practicable, to keep a record of rainfall during the year, and also to note anything affecting the crops during the year, and to report as fully as may be to your own Branch. In the case of most of the experiments, one year's trial will not settle the matter. Peculiarities of season, short rainfall, or an extra supply of moisture will have an effect, and must be taken into account. To be reliable and worthy of general adoption, experiments should extend over a period of at least three years. Failures as well as successes should be reported, as we learn not less by failure than success. Such work as I have indicated carefully conducted and tabulated, carried out throughout South Australia cannot fail to be of immense benefit to all engaged in the occupation of wheat-growing.

#### THE DISCUSSION.

Mr. H. G. Burton (Mangalo) mentioned that in the majority of instances in the new country the stripper was used for harvesting.

With this machine and the winnower it would be found a very difficult matter to satisfactorily harvest the small plots separately and expeditiously, as a separate heap had to be made for each.

Mr. A. H. Jeffries (Mount Bryan) congratulated the writer of the paper. There was no doubt that experimental work was of great value, but with the "one-man" farm the farmer's time was fully occupied in other ways.

Mr. N. S. Giles (Mount Remarkable) had conducted experiments for the Branch to which he belonged, and believed that the average farmer could do the work involved with a very little extra expenditure of time proportionately above that involved in putting in the crop ordinarily. All that was necessary was a little extra care in the marking of boundaries. It was unwise to attempt to gather the grain from small plots with a stripper. The better course was to secure a complete harvester, even if a machine had to be borrowed for the purpose. An important point was to secure uniformity of land on which they were conducting tests. If one set of experiments were to be conducted in a paddock which had previously been under test plots, it was advisable to run the second plots across the first.

Mr. W. Gum (Amyton) mentioned that he had spent 28 years in the North, and he was now more convinced than ever that it was essential that farmers should conduct tests to ascertain the most suitable methods of working their holdings. The suggestions of the writer of the paper were excellent.

Mr. J. J. Foale (Parilla), who was conducting tests for the Parilla Branch, said the difficulty of the lack of time on the "one-man" farm, had been got over in his district by the Branch appointing a committee of three to assist in the operations.

Mr. H. H. Davie (Mount Remarkable) mentioned that his Branch had set out to conduct experiments with the objective of securing by means of selection the highest quality of seed wheat. He made the suggestion that the products of the experiments of different Branches should be displayed on a stand set aside for the purpose at the Adelaide Show.

Professor Perkins suggested that Branches were well advised not to set out to do too much at the beginning, because if the experimental work was to be of any value, it must be done thoroughly and methodically, and on lines similar to those suggested by Mr. Pearce. They could easily extend the scope of their tests at any time. There was a danger with some experimentalists that they were out after big results, but they should have to take things as they came. The truth was wanted. It had been suggested to him when results were bad that they should be ploughed under; but that was not the way.

to do the work. Whether the results were good or bad they should be published. Further, it should be noted that results were of little value unless they extended over a number of years. Three years even was too short a time from which to draw conclusions. He suggested that the tests should extend over seven years. Any seven consecutive years in the history of the State would be found to represent fair average conditions. Another point was the permanency or otherwise of the plots. Manure plots, in addition to cultivation plots, should be permanent. The most satisfactory method was to have twin plots, one half being under fallow and the other half under crop each year. Mr. Smith, the chairman of the Experimental Committee, had said he was sure the committee would have the sympathy and co-operation of the officers of the Agricultural Department. He could assure them that that certainly would be the case, and personally anything that could be done to assist them he would certainly do. One delegate had referred to the difficulty of dealing with results from small plots where the stripper was used. They all recognised that in new country the stripper had to be used, and probably Mr. Spafford, who had had considerable experience with the stripper, would be able to give them hints as to how best to do the work. He was sure that with only a few plots just as exact results could be got with the stripper as with the harvester. The stripper was undoubtedly the best implement for experimental purposes.

Mr. W. J. Spafford (Superintendent of Agricultural Experimental Work) said when only one variety of wheat was being dealt with it was nearly as simple to use the stripper as to use the harvester. In using the stripper for a number of plots the heaps should be put as close together as possible on the one floor, and then they were nearly as easy to handle as one heap. To simplify the handling it was advisable to put bags under the grader of the winnower to collect the screenings. If they had a number of plots to handle the fitting of a couple of wheels to the winnower would expedite the work. For the handling of different varieties of wheat, especially if they were required for seed, it was essential to use the stripper and winnower, as it was practically impossible to clean the harvester. In growing different varieties of grain it would, in order to keep them pure, pay to use the stripper and winnower. In fact, it was the only method of keeping them pure.

Mr. Coleman said that very often, owing to the variation in soil and rainfall, what applied as regarded varieties of wheat, &c., to a farm in one district did not apply to others in another district. Therefore he was glad indeed to see experimental work being under-

taken by the farmers. In a season such as the present, for instance, it would be well to note any sort of wheat or grass that seemed to be standing the dry weather better than others.

Mr. Pearce, in reply, said he recognised the difficulty which had been mentioned of harvesting a number of plots with the stripper. But if they kept the number of experiments within their reach he thought that with a few plots it could be managed even if a tarpaulin to receive the wheat had to be used. The idea of Mr. Giles as to cross-working the land was very good, but, of course, Professor Perkins' plan of having twin plots was better, although the latter required more work. In manure tests it would be necessary to pickle all the grain alike. The only difference made must be in regard to the matter they were trying to prove by the experiments. Someone had suggested, in testing varieties of wheat, that to sow the same quantity of seed was not fair, because some varieties stood freely and others did not. He admitted that difficulty, but if they sowed a greater quantity of one variety than they did of another it would not be a fair test. What was required was two tests—one of wheats known not to stool too well, and the other of varieties which stood freely.

#### EXPERIMENTAL WORK ON MIXED FARMS.

Mr. H. V. Sprigg (Morphett Vale) read a paper on "Experimental Work on Mixed Farms," as follows:—

The object of this paper is to promote or provoke a discussion on fodder growing for meat and lamb production, with a view to discovering the best method of conducting experiments in connection therewith. A season like the present must bring home more forcibly than a good one the necessity for supplementing our natural grasses by growing fodder crops. Those who have sown or will now sow, fodder crops, will probably find that their wool and meat will be their best crop, and also that it will always pay them to give it a far higher place in their farming operations than it now holds. There is no need to worry about the markets; the world wants and must have our wool and meat, and the seas are clear; in fact, everything points to improved markets. Summer fodders should be put in immediately after the first rain now; such as rape, mustard, sorghum, maize, Japanese millet, lucerne, &c.

This summer all the feed that can be grown will be wanted. In a good season it is possible to produce a good export lamb, off the grass, but if we are to produce both the quantity and quality that we should we must grow feed for them.

If we use the right breeds and feed them, we can produce an equal, if not superior, lamb to that of New Zealand in a shorter time, and consequently at a cheaper rate, but this means that we must devote some of our land cultivation and energy to fodder production. Should the bad seasons we are having be instrumental in convincing us that we should not devote all our cultivation to cereal growing, thereby depending on one class of farming—keeping all our eggs in one basket—it will not be an unmixed evil.

#### FODDER GROWING.

I believe that in the immediate future the bulk of the farming operations in the central district will be devoted to fodder growing and meat production. It is the most important agricultural question we have to face, and its importance justifies the establishment by the Agricultural Department of an experimental station to go thoroughly into fodder growing, manuring, and liming of grass lands and pastures, and the breeding, rearing, and feeding of sheep for meat production.

There is a feeling in some quarters that the farmer should experiment on the plot system, with exact measurements, weights, &c., on scientific lines. Also, we are told science is measurement, that no experiment has any real scientific value unless its conditions and results, in fact its synthesis, are subject to exact measurement. It is because I recognise the truth of this that I say the general farmer is not the one to conduct experiments on those lines. He has neither the facilities nor the knowledge to give his results a true scientific value.

Experts are continually warning us against definite conclusions from individual experiments and even when they are carried out over a series of years, under definite plans and conditions, the conclusions are rarely absolute. What, then, is the scientific value of experiments under indefinite conditions and varied plans and management? Although it does not apply so well to fodder growing for pasturing, the plot system does lend itself for testing various things, such as varieties of cereals. The form of experiment that best suits the mixed farmer's conditions is the field experiment, carried out as part of the ordinary farming operations, under the general conditions of his particular district, and I strongly advocate the farmer spending his best energy in doing this. The extent or scope of his experiments will, of course, depend upon his pocket and his pluck. If under a fodder-growing rotation the fertility of the farm is improved, the cereal production maintained,

the lamb and wool production materially increased both in quantity and quality, and the net profits are higher, that is the measurement that must appeal to all.

We all admit we should have some sheep on the farm, and that it would be a good thing if we could grow fodder crops, but some say our summers are too dry, and that fodder could not be grown without irrigation. Before such a conclusion as this is arrived at it is obviously necessary to thoroughly test the matter over a series of seasons. It would be absurd to condemn a practice or proposal on the results of one season.

In looking over reports of papers read at our Bureaux, one is continually coming across the expression, "That a flock of sheep is very useful, or, perhaps, even necessary on the farm, as scavengers to clean up the fallows." Now, why should the main use and value of sheep be regarded as and degraded to the position of simple scavengers? I say that this Cinderella of our industries will soon be regarded as the main line, and that the bulk of operations will be devoted to securing for them the conditions and fodders they deserve.

Again, how can they "act as scavengers on fallows" if the summers are too dry to grow anything? Many farmers have to put in a lot of time and labor in destroying fallow growths; well, instead of growing weeds, grow fodder crops, and drive them to market as meat. As the conditions in individual districts vary so much, it is not practicable to lay down exact methods of testing various phases of mixed farming, or to definitely state what fodders or plants to grow. If that were possible there would be no need for this paper. I would, however, suggest that every farmer should devote a portion of the land he usually has under bare fallow to growing some kind of feed crop. In his choice of what to sow he must, by his knowledge of his district, put in something that is known to thrive, and then include other things to form the experiment.

I am a strong advocate of mixed fodders. Besides giving a higher feeding and fattening value, there is less risk of failure of the crop, and the only extra cost is the seed. With whatever you decide to make the main crop, mix whatever others you wish to experiment with. If your land is to be out for a year or so in grass, try some perennial grasses and clovers; if it is on fallow, stick to annuals. It is always a good plan to sow about a bushel of barley or oats mixed with your seeds, the result will more than pay for itself.

The portion of fallow put under fodder rotation instead of leaving it as bare fallow, will be as easily prepared for seeding as bare fallow, and the resultant crop will be equal or almost equal, whilst the net result will be higher than from the bare fallow. The best method of sowing small seeds with the drill is to mix them with the manure, and to sow them as shallow as possible.

#### MANURING AND LIMING.

In reference to the manuring and liming of our pastures and grass lands there is room for a lot of experimenting by the farmers. The quality and quantity of our grasses, and the stock-carrying and fattening capacity of our pastures can be materially increased by the application of superphosphates and lime. For these experiments I would suggest on pasture land, after the first summer rains, disc drilling a few cwt. of super. per acre. On most of our grass lands the quality of the feed would be much improved and the quantity greatly increased. Experiments in other parts of the world have proved that pastures so treated are much more palatable, and stock will feed off those portions in preference to any other. In the hills lands and in the southern districts the poor fattening value of the fodders is due to lack of lime in the soil in most instances. For this reason I suggest experimenting by a means of plots. I would mark off a few acres of pasture land, and, before the growing season, apply from half to one ton of lime per acre. This test could be extended to three plots. One with lime, one with super, and one with both lime and super. In the last case some time should elapse between the application of the lime and super., which could be added as a top dressing after rain had started the grass.

The South Australian farmer has shown that cereals can be grown in average seasons, under climatic conditions that some years ago were deemed prohibitive; if they tackle fodder growing in the same spirit they will be rewarded by a similar success. It should hardly be necessary to say that no fodder crop or pasture should be over stocked or fed too close. For the best results small paddocks are essential, i.e., paddocks proportionate to the size of the flock.

In conclusion, I may say that when I undertook to write this paper, I hoped to be able to give some concrete examples of results of experiments with fodders on my farm, but the unprecedentedly dry season has so checked the growth that no reliable deductions can at present be made.

## THE DISCUSSION.

Mr. H. Ledger (Pinnaroo) had conducted experiments in the growth of fodder crops for sheep, and he felt sure that this would be found a most payable system in his district.

Mr. J. Parkes (Waikerie) expressed the view that the experiment conducted by the individual would be of greater value than that conducted by the Branch. A three-chain road would in some instances be found to separate lands of an entirely different nature, and the requirements of one might differ very materially from those of the other.

Mr. F. M. McMillan (Bookpurnong East) had noticed that superphosphate destroyed the germinating power of rape seed. He therefore advised sowing these separately.

Mr. A. M. Dawkins (Advisory Board) congratulated the writer on the sound commonsense of the paper. The system of farming generally adopted in the Gawler River district was fallow, wheat, and grazing in rotation; but landholders were coming to the conclusion that to sow on the stubbles something that would give a profitable crop of feed for stock was the correct way to make the most of their land. This year he sowed 100 acres of a mixture of rape, barley, and oats at the beginning of March and April. During May and June he had 36 head of cattle on the land, and it was now carrying 8 horses, 80 sheep, and a few head of cattle. In reference to the matter of sowing rape, he mentioned that it was the free phosphoric acid in the super, which destroyed the germinating power of the seed. Colonial-made super. was treated with carbonate of lime, to take up this free acid; it was therefore free-running, and contained no injurious substances.

Mr. J. M. Hudd (Hartley) made a practice of growing fodder crops on the fallow. Last year he sowed 8 acres of maize, and this had provided excellent feed for horses and cattle up to the beginning of April. It had been urged that by sowing these crops he was depleting the moisture available in the fallow, but this year the land that had previously carried maize produced a better crop than that on the bare fallow.

Mr. Sprigg, in reply, said there should be no difficulty in sowing rape seed and manure together, if the manure were dry, and the mixing was done on the same day as the sowing. The seed should be drilled in as shallow as possible.

## EXPERIMENTS AND DEMONSTRATIONS IN THE ORCHARD.

Mr. E. S. Mathews read a paper on "Experimental Work in Our Gardens and Orchards," in the course of which he said:—

It is not in my province to dictate to the various sub-committees interested in experimental work in the orchards just what mode of procedure should be adopted. I leave that question to the practical ability of each Branch to work out on its own lines. Our Branch has appointed two members (practical men) to undertake a series of demonstrations, as follows:—Spraying, pruning, manuring of vines, use of fertilisers, and tillage and fallow. The results of this series of tests, extending over a given period, is bound to result in benefit and improved methods.

There are many other important matters which could receive attention and demonstration, viz.—The effect of drainage on the soil, and a system of irrigation for dry seasons. Good subjects for demonstrations are "Explosives," followed by the application of fertilisers and by irrigation; winter v. summer pruning; the ploughing-in of manures at various depths and at different seasons of the year. Then the effect of peas as a leguminous crop for green manuring might well be tested, and yearly tests of different manures made. At present most orchardists use their own fancy without having proved which are the best, and thus lose valuable time and money. In the various methods of pruning care should be taken that the same varieties of fruit trees (be they pear, apple, apricot, or peach) are taken for the test, and what is more, as near as possible the soil, situation, and cultivation should be similar. I suggest small blocks of fruit trees standing together in preference to rows or alternate rows. This applies more to manuring and spraying. Where possible an analysis of the soil should be taken, otherwise we may be employing ingredients the soil is already rich in. The tests in one part of an orchard have but a slight bearing on another part. As an illustration of this, note the difference between strawberries grown at Mount Lofty and those at Upper Sturt; or the coloring of a Maria von Houtte rose in different gardens. So many factors are operating in Nature which are calculated to upset tests, unless carefully noted. Our rainfall is most important in a series of tests. Frosts, again, play an important part, hail and winds, hot winds—any excess of either of these in a given season may upset our results unless carefully observed and duly tabulated. A better system of testing the value of the different brands of arsenate of lead now on the market might well be instituted. Each man has his fancy, but no positive results have been obtained.

When best to spray, number of sprayings, and just the most opportune time are included in a few of the many tests that could be carried out with thoroughness. I know I shall be told all this has been done, but I reply that so few are proving for themselves and others the worth of some methods and the worthlessness of others. Care should always be taken that spraying should be done when least injurious to bee life. For tests to be effective, trustworthy, and reliable, a system of keen observation, untiring energy, and a cheerful giving of valuable time are necessary to make the results complete.

I know that much of this has been done for us by our expert scientific men, but what I am impressed most with is the fact that many have not availed themselves of this knowledge by personal demonstrations, and until they do they prefer a "way of their own." The formation of an experimental committee at last year's Congress marks a great step to further knowledge and the usefulness of members of Branch Bureaus.

#### THE PAPER DISCUSSED.

Mr. F. Basey (Renmark) said that his Branch had conducted experiments this year for the first time. Especially in his own particular line—growing raisins—experiments in manuring had to be very carefully carried out. The fruit had to be kept apart and the dry weight taken. The same thing applied to other fruits and one difficulty was that the whole crop was never gathered at the one time. Take pears, for example. A few might be picked off one tree, then some of the fruit on other trees gathered, and then some more off the first tree. The difficulty, therefore, was to keep the fruit from the different trees separate. However, the members of his Branch were doing their best, and they hoped to do good practical work later on.

Mr. George Quinn (Horticultural Instructor) said the last speaker had hit the nail on the head with regard to experiments in the orchard. The attention which had to be given to details and the time over which they had to be carried out were the outstanding difficulties. A cereal crop was reaped at once, but in the case of a fruit crop, harvesting was spread over a long period, only a few fruit, perhaps, being taken off a tree at a time. Therefore, unless one had the time, the means, natural inclination, and tenacity of purpose, he was likely to give up before sufficient time had elapsed to prove the value of the experiment undertaken. His department had been carrying out a lot of experiments in different orchards,

but he felt very diffident about saying anything in regard to them until the results were established—say 8 to 10 years. That seemed a long time to wait, but as fruit-growing would be carried on in South Australia for a great number of years, the work should be of ultimate benefit. Casual experiments in regard to manuring, spraying, &c., often gave rise to misleading impressions. They had had some striking examples of that. For instance, practically every fruitgrower he had spoken to had said that apples affected with bitter pit were more prevalent on the upright vigorous growth than on the pendulous laterals. A check had been kept at the Blackwood orchard, and last year it had been found that for that one year, at any rate, the opposite was the case. Then, in regard to codlin moth. The bulk of opinion was that the caterpillars went in at the calyx end of the fruit. Actual examination, however, had shown that opinion to be wrong. The bulk of the caterpillars did not go in at the calyx end. It had been proved at experimental stations in the United Kingdom that generally accepted opinions were often wrong.

#### AFTERNOON SESSION.

Mr. G. R. Laffer, M.P. (Chairman of the Advisory Board) presided over a large attendance of delegates.

#### “THE BEASTIE OF THE GOLDEN HOOF.”

Mr. Henshaw Jackson, Wool Instructor, Adelaide School of Mines and Industries, read the following paper:—

In addressing this conference regarding the animal which, more than anything else has given Australia its position in the world's commerce, I do so with the express desire to direct attention to the sheep as an economic factor on the farm, and to have you regard it in a somewhat different fashion from that which has hitherto obtained in this country. That which I have to say on the subject is intended to refer only to small flocks in which I, in common with many others, take the keenest interest, and hope to see largely increased in numbers during the next decade.

Except in the case of those who in the past have done a great work in Australia in establishing our world-famous flocks, and those who are carrying on that work to-day, sheep have been taken very much as a matter of course. We have become so accustomed to the fact that fortunes have been made out of sheep, and that an-

nual dividends of "Golden Fleece" still come in from outback, that we do not bother to get any closer to them than they permit when roaming over the huge pastoral areas of the State. In these circumstances it is not surprising that we do not fully understand the sheep in its relation to the necessities of civilization and what a valuable factor it is in the sum total of things.

The big squatter in Australia is being pushed further out, where there is available the necessary expanse of country requisite for his particular methods of growing sheep and wool, and flocks are becoming distributed through many hands. This presages a gradual change in the methods of sheep-raising, and a greater spread of knowledge respecting the profitable handling of small flocks on small areas.

#### A PROFIT-PRODUCING ANIMAL.

So far as sheep and wool are concerned we need never fear over production; the wants of the world in wool and mutton, not to mention tallow and other by-products, are increasing every year, and it is possible to deduce from current statistics that the all-round demand is, if anything, ahead of the supply.

In face of these things, and in spite of the economic value of the sheep, we still hear of sheepless farms and read of cases in which farmers have actually had to borrow sheep from their neighbors to eat down the excessive growth of feed appearing on their holdings in good seasons. Such a state of things points to ignorance or carelessness regarding the attributes of sheep. If only for its food value the sheep stands out above all other animals. None excels it in the production of a cheap, wholesome, and highly nutritious article of diet, although the pig is greatly favored in some countries, and perhaps in such places pork rivals mutton in the popular taste. We have the authority of the world's greatest food chemist, Professor Liebig, that mutton is superior to pork in the formation of vigorous, healthy muscle, while its tendency to engender inflammatory and putrid diseases is considerably less.

Looking into the profit-making capacity of the sheep, compared with other stock, it wins under nearly all conditions. Take the risk of loss by death. Through ordinary causes it is practically nil. It is hard, however, to state a percentage, because, as a matter of fact a sheep never dies insolvent; but if we lose a colt or a cow after the trouble of rearing it to a useful or productive age, the loss is practically a total one, all our time and trouble having gone for nothing. save, perhaps, a hide worth a few shillings, which is infinitesimal

compared with the live value of the beast lost. If a sheep dies at any age the wool then on its body, or that which it has already produced, far more than covers all it ever cost its owner.

The droppings of sheep, in this country at any rate, are taken very little into consideration, although in point of worth they stand next in value to pig and fowl manure. The droppings of cows and horses are prized far more, but are not nearly so useful. The soft, porous excrements of large stock when exposed to the action of sun and wind lose most of their fertilising properties by atmospheric evaporation, which in Australia is very great. Sheep manure, on the other hand, is naturally protected by a sort of mucous covering which prevents any action of the atmosphere from stultifying its fertilising qualities, which remain until the dung is well trodden into and incorporated with the soil.

Then, where can we get a better land-cleaner than sheep? They will clear up new ground or neglected old lands, and practically pay for doing it. Sheep delight to browse on buds and green shoots, and will strip the bark off most shrubs which are a pest to farming. Land which has been depastured by sheep is always improved, and in some peculiar way seems to be benefited more than by having other stock running on it. All wild and poor grasses gradually disappear and are succeeded by better ones where sheep are kept, while the sward becomes very dense and even.

So far as wool production is concerned I am not prepared to advocate the keeping of sheep by farmers for wool alone, although there have been periods in which a profitable return has been made solely from the fleece. It is quite possible that wool prices will keep at a payable level for some time, but it seems to be almost certain that mutton prices will keep steady, and even with a great increase in our flocks the outside demand for meat will go far to prevent any slump in values.

#### CLASS OF SHEEP FOR THE FARMER.

Relatively to the kind of sheep to keep, it looks as though, so far as the farmer is concerned, the most profitable animal of the future must be first of all a mutton producer. At the same time I would point out that it is, without searching for the mythical dual purpose animal, quite possible to produce sheep with the capacity of growing valuable wool of a class, and a carcass that will count well with the butcher.

With the right class of sheep for the particular district, and a community of interest established by farmers agreeing to breed

that class throughout, it should be quite possible to secure a return of £1 a head for each breeding ewe on the farm.

If we were to set our minds in the direction of an agricultural industry, such as is to be found in Britain and Europe, the keeping of sheep and other live stock would gradually become general, production would be stimulated, and there would be more likelihood of the young men staying on the farm. With an interest in the breeding of sheep, a knowledge of their requirements in feed and attention generally, by which occupation light and enjoyable can be obtained for every month of the year, the future generations of our farmers will become as much a part of their particular district as are the old yeomanry of England, and we shall have a country life as attractive to all sane-minded people as can be found anywhere in the world to-day.

To attain the highest degree of prosperity live stock on the farm are essential, and while I advocate that sheep form a large proportion of such stock, I am not prepared to say that all farms should be given exclusively to sheep, although it is more than likely that a farm devoting its whole capacity to sheep would show better results in that department than one where they were regarded only as a side issue.

Sheep have peculiarities of their own already mentioned which render them almost indispensable on a farm, and some farmers will have them mainly as weed-destroyers, without any further thought as to their economic value. I dare say that in some places as much grain will be lost in harvesting as would send 50 or 100 sheep off the farm as prime. Sheep put more of what they eat into marketable profits than any other animal; this of course is mainly because they can be turned off sooner and made to bring their highest price any time between three months and a year old. When they have finished growing you can have them ready for sale, and gains made by an animal that is growing are naturally cheaper than those made from one already mature.

Sheep farming meets its biggest obstacle in the lack of understanding as to what a sheep can really do, and we have got to get it out of our heads that sheep belong only to large areas or rough country, on which nothing else will thrive. I cannot say what the proportion of sheep to acres is for the whole of South Australia, but I believe that in Great Britain the figures are something like one breeding ewe to every one and four-fifth acres.

By the intelligent handling of land for the production of crops and wise management of the flocks it should be easily possible to

raise lamb and mutton at a cost that will allow a nice margin of profit. Each lot of sheep sold would improve the land each year, and so make the cost of production still lower.

Sheep work is light and pleasant, and to those who will give it the necessary study, quite absorbing.

#### BREEDING UP A FLOCK.

Bearing in mind the above generalisations regarding the value of sheep to farmers, we may now shortly consider some facts about breeding. Many agriculturists on first turning their attention to sheep may at the outset find themselves in possession of a flock of which the outstanding feature is that of neglect. From such a lot of sheep it would be practically impossible to select ewes that could be termed first-class, but as a beginning must be made towards improvement and breeding up, a first-class and second-class division will have to be decided upon. To do this we must select those ewes which nearest approach the good points of carcass and wool, and place them at the head of our flock. If the sheep have any good blood in their make-up, if mated to superior rams of the correct type, they will most likely produce a much-improved crop of lambs to advance the flock upon its initial stage of progress.

In making the division, by-the-way, no ewe defective in both carcass and wool should be admitted to either class, and even if a ewe showing double faults in this respect should be closely related to sheep of long pedigree and high breeding, she must be rejected, unless it happens to be drought time, when it becomes a matter of necessity to retain every ewe capable of producing a lamb. Droughts, however, should not affect sheep farmers to the same degree as they do the larger breeders, and in small well-tended flocks should not be of serious concern.

From the foundation laid by the selection and mating of our sheep we go on to better things each year; but we must always keep the best ewes. This is the fundamental basis of success. The reasons for this course are fairly obvious; nobody needs telling that if he sells his best ewes, the man who buys them will have better sheep than he. Supposing a sheep farmer having 50 ewes should sell the 10 best of them; it may take years of breeding to get another 10 like them. This is all so much time lost, and is a disadvantage which affects the sheep farmer more than the pastoralist on account of the difference in numbers of sheep from which to select. It is at times rather difficult to resist what seems a tempting bid for a good ewe, but when thinking the offer over, it is a good plan to remember that, not only do we sell the ewe, but also her possible

valuable increase. It is all right to sell some A1 ewes when as a whole we have brought the flock to such a plane of excellence that we shall not notice their removal, but until we have arrived at that stage we must in our own interests keep the best of the best for our own breeding. Of course some ewes have to be sold every year, but make the selection of sale sheep carefully, and of all times in the 12 months winter is probably the best because that season is the test of a sheep's condition, and if we have kept proper observation of our flock we can at this time see at a glance those animals not up to the mark in vigor and constitution, and which are not carrying their lambs so well.

Any sheep failing in essential maternal qualities may be profitably dispensed with, for though a ewe may look well and hearty, if she is a bad breeder and poor mother she is no more valuable than a wether, and makes a better showing as mutton than as a member of the breeding flock. Sometimes ewes are kept because they look good and fat, but often their plumpness and good condition are gained at the expense of their lambs—if they had any—and the loss in keeping them is double, because they are keeping better sheep off the farm, and themselves producing starveling lambs, which, if they reach maturity, only serve to perpetuate the faults of their dams.

#### ATTENTION TO DETAILS.

In all cases where it is decided to have sheep on the farm, the fullest measure of success can be achieved only when they are regarded as a factor, and not as a circumstance depending upon seasons. Care and attention to details are just as necessary in regard to keeping breeding sheep as with any other department of the agricultural industry. We know very well that wheat farmers who make a point of selecting the plumpest and soundest grain for seed, will, other things being equal, reap a better crop than the man who is satisfied to plant ungraded wheat of all shapes and sizes, cracked and whole. In the same way sheep farmers, by systematising the culling and selection of sheep can advance their flocks to the highest level of production and check to a very large extent any serious deterioration of their animals.

A wheat farmer may not very well take note of every stool which produces the greatest number of plump, well-filled heads, but a sheep farmer should know the capacity of every breeding ewe on the farm if he desires to get rid of the passengers. For this purpose a proper system of numbering and registration should be adopted, and though at first sight this may seem unnecessary, a little thought shows it will prove of great convenience, and gradually lead to methodical

handling of the flock in such a way as will largely assist the efforts to improve the farm sheep. Definite and precise results can be obtained that rule of thumb will never give.

All sheep breeders, large or small, who stick to one strain of blood, find sooner or later, that they are compelled to breed in and in, or otherwise to import a fresh strain. Either method carried too far is bad, and therefore undesirable. By adopting a proper system of numbering and registration we know where we are at any time, and can go on inbreeding for a longer period with less risk, or change the relationship of our animals at the right time and with the proper families. Few men relying on memory alone, and using half a dozen rams in their flocks the same season could say, years afterwards, what the actual relationship of the sheep to each other would be.

A very safe plan to adopt when founding a flock is to start a systematic method of registration and numbering that will show at a glance the sire and dam of any sheep in the flock, the date of lambing, the number of the progeny, together with any remarks necessary regarding the lamb's quality and appearance, and the milking capacity and motherliness of the dam.

The numbering and registration will then go on from year to year, and if careful watch is kept at lambing and shearing times, the resulting progeny and wool being noted and analysed, the flock should go up a fresh notch each season.

In this connection it is worthy of note that poultry and dairy farmers think it wise to analyse and check results in the egg and milk business. If it is worth while for them, why not for the sheep farmer?

#### DELEGATES' OPINIONS.

Mr. J. Gray (Claypan Bore) thought Congress was indebted to Mr. Jackson for his paper. Some 18 months ago he (the speaker) had bought a small flock of sheep at Bordertown. As they knew, South-Eastern sheep had small carcasses, but in the flock was a ewe from Canowie. From that particular ewe he got a lamb which returned £1, and the wool from the ewe weighed 15lbs. and realised 10s., making a total return of 30s. from that ewe, whereas the average return from the whole flock was 18s. In the Pinnaroo district there were a number of white sandhills. Last April he had ploughed a paddock containing these, and had sown it with Algerian oats. Now he was carrying on 200 acres, with 60 acres of sand, 200 sheep and 100 lambs. The white sand was not good wheat-growing land, so if it could carry a sheep to the acre by treating it as he had described,

it turned that kind of land to profitable account. He was confident if that sandy land was sown with oats and sheep kept on it, the return would be much greater than would be got from growing wheat on it. It also improved the land for subsequent cropping. Last year he had reaped 15 bushels per acre from land that had previously been treated as he had said.

Mr. H. V. Sprigg (Morphett Vale) asked whether the second-cross lambs were not the best for export. The Crossbred ewes were different to the Merino in that they would settle down and eat out one place instead of roaming all over the country.

Mr. W. J. Colebatch (Principal Roseworthy College) said the importance of having sheep on the farm had been reiterated by Professor Lowrie, the late Director, at conference after conference, but they still seemed to be going ahead very slowly. The reason, he thought, was because farmers had great difficulty in getting the right class of ewe. (Applause.) It seemed that the squatters here had not done anything to produce the class of ewes the farmers required for lamb production. In New Zealand, on the other hand, there were annual half-bred sales, and these were attended largely by farmers. It seemed to him that it would be well for some of the larger farmers to go in for breeding half-bred ewes, so that they might be available for the smaller farmers. When at Kybybolite he had had great difficulty in getting the class of ewes wanted, and, in fact, he did not succeed in doing so. Farmers could grow the fodder necessary, but could not, owing to this difficulty, produce the lambs. In dealing with small flocks they would find that they had to give them just as much attention as they did to their calves and pigs. (Applause.)

Mr. J. A. Lock (Keith) said his experience of sheep in the South-East was that the Crossbreds did the best. The lambs developed quicker, and did better than the Merino. He thought farmers should pay more attention to growing fodder crops.

Mr. Thomas, jun., said that after three years' experience he had gone in for English Leicesters. Their country was a scanty feed country, and their English Leicesters had this year proved themselves equal to the occasion and ate anything. It was well to remember that the land sometimes got sheep sick, and to therefore give their paddocks a spell.

Mr. Jackson, in reply, said he agreed with Mr. Sprigg as to the second-cross lambs. Mr. Colebatch had put his hand on the weak spot when he referred to the difficulty of procuring the right class of ewe. He (Mr. Jackson) had asked a pastoralist whether it would not pay the pastoralists to pick out some of their old ewes, get a

few Lincoln or Leicester rams, and produce the class of ewe the farmers required. The objection of the pastoralists, however, seemed to be that they did not have sufficient small paddocks to prevent the Lincoln or Leicester rams getting access to their main flocks.

### CO-OPERATION.

Mr. S. Nairn (Stockport) read the following paper entitled "Co-operation: Its Possibilities and What it has Accomplished":—

In recent years probably no other work, having for its definite and specific aim the material advancement of the community, has received greater attention than has "Co-operation." Gradually its immense possibilities for good have won widespread recognition, and now the principle underlying it is being applied with remarkable results in practically all parts of the world. In the aggregate there are hundreds of thousands of co-operative organisations of one kind and another, and there is no doubt that they have contributed enormously to the prosperity and happiness of millions of people.

In setting out to prepare a paper on "Co-operation," the chief difficulty which confronts one is to determine just where to begin and where to conclude. The theme presents a wonderful field for study and analysis, and the more deeply one probes into it the more one realises the utter impossibility of dealing comprehensively and thoroughly with the multitude of aspects in anything less than a small newspaper. Therefore I have resolved briefly to outline the history of the movement in relation to the primary industries, indicate the character of the expansion which has occurred, describe the inauguration and growth of co-operative effort under the Southern Cross, and suggest some directions in which it might be utilised to promote the welfare of South Australian men on the land.

It would appear that the need for co-operation among the primary producers was first forced upon the minds of economists in Great Britain by the disadvantageous conditions under which the small men were laboring. In Ireland the movement owes its inception to Sir Horace Plunkett, who saw that the small agriculturists in that country would never be raised until they were released from the clutches of the userer, otherwise known as the "Gombeem-Man." To win for "Co-operation" the recognition and appreciation which it merited, however, required much enthusiasm and unlimited resource, and it is a significant fact that 100 meetings were necessary before co-operative creameries were brought into existence. Some of the branches of the National Society failed, as might be expected, but

in each instance the reason lay not in anything innately wrong with the organisation itself, but in the lukewarmness of some of the members. That lukewarmness, by the way, has more failures to its credit, in every department of life, than probably any other thing.

Concomitant with that in Ireland, agricultural co-operation has advanced by leaps and bounds in England, Wales, and Scotland. Twenty-five years ago there was not a central agricultural organisation society in the three kingdoms. Now there is one in each. Affiliated with that in Ireland are 330 odd co-operative creameries, 151 agricultural societies, 240 credit societies, 50 industry societies, 25 poultry societies, and many others.

The aggregate annual turnover of the societies exceeds two millions. It is claimed that "Co-operation" has cut down the prices of artificial manures from 20 per cent. to 40 per cent. "The wiseacres scoffed at our toy banks," writes the secretary of the Irish Agricultural Organisation Society, "but in spite of sneers, our capitalisation of honesty remains the one most valuable asset." The "greatest effect" of the co-operative movement, he adds, is that "it has taught the people to think; it has made them self-reliant, business-like, and industrious." The little banks have advanced over a quarter of a million without loss. The "Gombeem-Man" no longer has all the countryside in his hands. Tattered peasants at co-operative meetings may be found expressing themselves in decimal points, and calculating the value of soluble phosphates at so much per unit. Political and religious barriers have also been broken down in a wonderful way by co-operative activity. There is no question on the part of any impartial inquirer regarding the vast amount of good which has been done economically and from a social point of view. Co-operation, by offering men capital, seeds, implements, and manures at reasonable prices, by practical methods of marketing, by interesting people of one part of the country in the doings of those in other parts, and generally by widening the popular outlook, has prepared the way for taking the utmost advantage of new land legislation.

In England the growth of co-operation in the rural areas has been almost as marked as on the other side of the Bristol Channel. The largest of the 200 odd societies affiliated with the British Agricultural Organisation Society is the Eastern Counties Farmers' Co-operative Association, which was established only 10 years ago. Although the called-up capital is only approximately £1,000, its sales, even as far back as 1907, amounted to nearly £200,000. There are something like 700 members, farming an average of 309 acres,

a striking argument in reply to those who suggest that "Co-operation" has nothing to offer the large farmers. The work of the association, which is affiliated with the Co-operative Wholesale Society, as well as with the Agricultural Organisation Society, is managed by a trading committee of farmers, with a competent staff. The association's pig ledger shows an average total of £4,000 per month. The organisation has a pig buyer, who visits the pig markets all over the country, protects in a notable way the members' interests against "rings," and provides expert advice relatively to feeding and the requirements of the market. The average profit aimed at by the association in its transactions is  $2\frac{1}{2}$  per cent., which has been found to be sufficient to cover all working expenses and interest on share capital, and to allow a substantial sum to be placed to reserve. On oilcakes and feed stuffs the commission is less than  $2\frac{1}{2}$  per cent., and in one year more than 10,000 sacks of corn were sold for members at Mark Lane. The association supplies its members with everything they need, including agricultural implements and engines, fencing wire, paint, and artificial manure. Local trading committees are formed in suitable districts, and very few firms now refuse to supply the association.

#### CONTINENTAL EXAMPLES.

As most members are aware, the most remarkable development of agricultural co-operation has been witnessed by the Continent of Europe. In Denmark, for example, there is a co-operative dairy in almost every parish (1,101), and 36 co-operative bacon factories. The success of the Danish trade in eggs, as, indeed, the trade in eggs in every other Continental country, is due to co-operative methods. In 1907 the eight Danish societies exported 14,000,000 eggs. It is no unusual thing for a Danish farmer to belong to 10 local co-operative societies, covering in their activities an exceedingly wide range. As far back as 1903, there were more than 17,000 co-operative societies in the German Empire, while in France, Belgium, Holland, and Italy the co-operative movement has also spread with startling rapidity, and has been distinguished by a gratifying success.

One phase of co-operation which appears to be destined to prove of great benefit in various parts of Europe is that having for its object the improvement of livestock. The principal means by which that is accomplished is by the purchasing of bulls and stallions and the keeping of herd books. The animals bought by the co-operative societies—the members of which are bound to keep only their best cows and heifers and mares—are entrusted to a keeper for a de-

finite sum. All moneys received, prizes, and subvention fees belong to the society. Sometimes the keeper has an interest in the business and a share of the profits. When the society has not always the means necessary for the purchase of the bull or stallion, it has recourse to agricultural credit. By the adoption of some such system in South Australia much could be done, especially on the swamp and irrigation areas, where the settlers are closer together, immeasurably to improve the standard of the cows kept and the productivity of the herds as a whole.

Of the numerous agricultural co-operative associations in Italy, the most thriving and successful is the Cremona Consortium. This was founded in 1896, with 160 members, and a capital of £360. To-day it has 16,000 members, with a capital of more than £4,000, and during the last couple of years it has been delivering annually about £120,000 worth of goods. Its consignments to members each year comprise more than 11,000 tons of superphosphates, £1,000 worth of nitrate of soda, £10,000 worth of various other chemical manures, and almost £12,000 worth of machinery, and many thousands of pounds worth of grain and seeds for sowing. The consortium has not confined itself to the work of purchase and sale, but has tried to derive the best moral results from association. In fact, it has shared to the extent of £200 in the foundation of an agricultural mechanical school, paid out £40 for purposes of live-stock improvement, £60 for rural telephones, and £20 in behalf of an anti-phylloxera consortium. Besides, there appear in its accounts annually an amount of £80 for experimental farming, another of from £80 to £160 for contributions to livestock shows and studs. All this the Cremona Agricultural Consortium has been able to do by limiting its interest on shares to 3 per cent., while its members have renounced all participation at the end of the year in the surplus credits in proportion to the purchases, habitual in institutions of this kind.

In those older countries the most important factor in popularising co-operative enterprise, and in facilitating its progress, have been what are generally known as the "credit banks," institutions established primarily to enable the smaller producer to obtain financial assistance readily and at reasonable rates. At one period it was not uncommon for the "Gombeens-Men" to demand on loans interest as high as 90 per cent., and there is cited the case of a farmer in Ireland who was asked to pay something over £6 10s. on a bill of £4 15s. for three months. In Germany the value of purchases of agricultural necessities through the German Credit Bank has been

stated at more than £4,000,000. Although "Gombeën-Men" are not unknown in Australia, they do not constitute a serious problem in relation to the success of the primary producers, who, as a rule, enjoy happier conditions, probably, than prevail elsewhere in the world. Each year the various State Governments are manifesting an increasing desire to do all in their power financially, and in every other respect, to facilitate the settlement of the land, and to enable holders to bring their properties to the regular profit-making stage, without having to suffer otherwise unavoidable disabilities. When the limit of the Government help is reached, the banks and other institutions generally are prepared on good security to advance money on reasonable terms, so that, except when a succession of unfavorable seasons is experienced, failures through lack of ready capital are extremely rare. In the circumstances, therefore, there is nothing like the same need in Australia for "credit banks" as exists in the more populous countries, where, in the main, the men on the land are often of a different calibre, and operate under almost entirely different conditions. That "credit banks" would prove to be exceedingly useful is practically certain, but for the reasons indicated, as well as for others, it is unlikely that for many years to come, at any rate, they will be widely adopted in the Commonwealth.

#### CO-OPERATION IN AUSTRALASIA.

The best illustration of effective co-operation on the part of the producers in Australasia is that furnished by the New Zealand Farmers' Co-operative Association, which has its headquarters at Canterbury, and has played a most noteworthy part in promoting the expansion and financial stability of that portion of the Dominion. It was inaugurated in 1881, "for the furtherance of the farming interests," and has achieved its purpose most effectually. The prospectus set out "that these interests would be served by offering facilities to the farmer for the storage and shipment of his produce to the home or other markets, and the appointment of agents in different localities for the furtherance of this object; grading and classification of shipments of produce in order to facilitate their sale at the most advantageous prices; effecting advances to members on any securities, real and personal, that the directors might think fit; acting as general merchants in procuring for sale to the shareholders cornsacks, implements, &c., and conducting the sales of the society on a cash basis."

That "co-operation" has not made greater headway in South Australia may be attributed to a large number of causes. In the

first place, our producers are an exceptionally independent body of men, more or less conservatively inclined, and having a deep-rooted preference for paddling their own canoes. The great majority of them are comfortably situated, so far as this world's goods are concerned, and they have rarely found it essential to work together on a broad business basis for the accomplishment of their own ends. There is plenty of evidence available, however, that they are by no means blind to the advantages which various systems of effective co-operation have to offer, and in the last few years, particularly, they have demonstrated that fact in many instances by associating themselves with co-operative organisations. The most important of these, of course, is the South Australian Farmers' Co-operative Union, which is steadily growing in favor and appreciation. Then there is the South Australian Fertiliser Company, which has just recently been established; and there are the branches of the Australian Dried Fruits Association, Co-operative Jam Factory, Co-operative Fruit Grading and Packing organisations, Co-operative Butter Factories, and the Co-operative Supply Stores, which have developed from the South Australian Fruitgrowers' and Market Gardeners' Association. All of these have had numerous difficulties to encounter, including especially the want of enthusiasm and loyalty on the part of members. Without these, of course, no society can possibly progress so satisfactorily as it would in other circumstances. Apart from those indicated, one reason, perhaps, why certain of the co-operative institutions have not gone ahead more rapidly is that they necessarily deal with products the prices of which depend more or less upon those in other parts of the world, and therefore are subject to marked fluctuations. In Europe the co-operative associations endeavor, so far as possible, to avoid all such things, and that policy explains in a large degree why they are able to conduct their enterprise at such low costs, comparatively speaking. Apparently the supply of artificial manures to the members at the lowest price forms a leading plank in the objective platforms of valuable and profitable features of its vast enterprise, and what has been achieved there can be accomplished in this State. Of course, the argument will be put forward that some men prefer one brand of super., and some another; but, after all, that seems to amount to merely a matter of preference or prejudice, as the case may be. If a certain manufacturer can turn out a first-class article, under similarly favorable conditions, surely another can place on the market a like product of an equally high standard. After all, the main factors in relation to superphosphate are the price, the percentage of soluble phosphates and freeness of running. Where

the two latter are on a par with those of other manures, the fertiliser which reveals an advantage in cost is the one every common-sense person may be relied upon to take.

Without discussing details any further, I have purposely refrained from quoting and analysing particular bases of co-operation, owing to their multifarious variety to suit special conditions. I shall conclude with the opinion that all things tend to emphasise the fact that the time has arrived when the Branches of the Agricultural Bureau should go exhaustively into the question of co-operation. If only they will devote to it the careful and unbiased thought which it undoubtedly merits, they will, I am convinced, soon perceive ways and means for securing unto themselves material benefits which at present they do not enjoy.

#### CO-OPERATIVE PURCHASE OF FARM MACHINERY, MANURES, ETC.

The following paper, prepared by Mr. M. L. Nolan and Mr. P. H. Knappstein (Clare) was read:—

The Australian people are too prosperous, paradoxical as this may sound. That it is true is a conclusion forced upon us when we observe the persistency with which a proved means is ignored of materially lessening the cost of both living and production. In Great Britain the members of the various classes of co-operative organisations, allowing for the families dependent on them, number eleven millions, or one in every four of the population. On the Continent, especially in France and Germany, the same state of things prevails. In fact, all over the civilised world—except in Australia—co-operative movements by virtue of their beneficial effects are embracing the people. When competent observers tell us that co-operation means a reduction in the cost of living of at least 10 per cent., surely we should consider whether we can afford to penalise ourselves by refusing to enjoy its benefits. We are being handicapped to the extent of the resulting loss as against our competitors in other lands who are enjoying its fruits. The time will surely come—perhaps much sooner than we think—when we shall not dare to remain in our present attitude of indifference. As things are, however, an appeal to South Australian producers on the general merits of co-operation would be futile and a waste of energy. But there is one phase of the matter where a very effective form of co-operation could be easily carried out. The method involved is so simple and the financial gain is so certain that it should impress the minds of members as being well worthy of a trial.

### A PRACTICAL ATTEMPT.

For some time past the Clare Branch has had under consideration the co-operative purchase of farm machinery, manures, &c. In these times of high and ever-increasing prices for almost all kinds of merchandise, not balanced, unfortunately, by corresponding value of the commodities we have to sell, it should be the duty, as it certainly is in the interest, of every producer to avail himself of any means whereby the cost of his instruments of production may be lessened. We need but to regard the large number of agents employed by the manufacturers and wholesale houses, the big commissions paid, the army of travellers speeding to and fro in their motor cars through the length and breadth of the land, and the many other unnecessary channels of expense, to realise the heavy and gratuitous tax placed upon the "man on the land." The producer has to pay every time; on his shoulders and on his alone does the burden fall.

Although saying that these heavy expenses are unnecessary, the fact is quite recognised that merchants can hardly help themselves. In these days of fierce trade competition what one does all must do; but could a method be adopted by which these outgoings might be prevented, sellers would certainly pass on the sums saved to the purchaser, for their net profit would still remain the same, and the cheaper the price the more numerous the sales would be. What then is the remedy? Our Branch believes that in the Bureau system of this State an admirable foundation exists for the co-operative purchase of all requisites of production, such as farm and garden implements and machines of every kind, engines, manures, and so forth. It is admitted that South Australian producers are right in the front as regards ability and methods of working, and that they are and will continue to be large users of the most improved instruments of production. Of these producers the very cream are, naturally, those in membership with the Bureau. To get into direct trade relations, through their Bureau Branches, with such a large number of the very "elite" of the producers would be an irresistible attraction to the average wholesaler.

### THE RESULTS OF INQUIRIES.

From our inquiries we feel justified in saying that the net saving to buyers on ordinary merchandise would be equal to the trade discount, and on certain lines where sales are attended with heavy expense and commissions the saving would be even greater.

We have been in communication with several of the large Adelaide houses that deal in the class of goods indicated, to ascertain their views on the matter. Favorable replies have been received from a sufficient number to ensure that almost any article required to aid production can be obtained at trade discount prices provided the order comes through the Branch secretary. Several firms are, however, remaining aloof from the proposal unless they

are given a collective guarantee by the Branch as a whole for all goods so purchased. Even where a firm does not insist on such a guarantee being given it is only right, in justice to the firm, that any Branch sending such orders should exercise a strict business-like supervision; but in requiring such an undertaking from members collectively we think that the sellers are quite justified, and it is on this point, if not made perfectly clear, that many delegates will join issue with us. It is therefore very necessary to set out plainly and explicitly the methods proposed to be adopted. They would be somewhat similar to those governing the Co-operative Credit Bank system.

#### A PRACTICAL PLAN.

Any Branch of the Bureau deciding to form itself into such a co-operative body would appoint a committee to consider and decide on every order submitted by members for co-operative purchase. In considering the applications the committee would be guided by business principles, regard being paid primarily to the character and standing and, secondly, to the financial stability of the applicant. Where the order would be a cash one, of course very little consideration would be necessary, but a rigid supervision would have to be exercised in passing orders for goods proposed to be bought on the time-payment or any other system involving a collective guarantee. The risk of loss would be practically nil, for all the existing conditions would make against it. In small centres the character and moral worth of everyone is well known; almost equally well known is his financial position, and with these safeguards to guide them the committee's decisions would be unerringly safe. All orders passed by the committee would be transmitted by the secretary to the firm dealing in that particular line of goods. No restriction would be placed upon the number of firms admitted into the system. The more the better.

We commend this branch of co-operative action to the careful consideration of the Congress, feeling assured that it is practically safe, easily worked, and helpful from the financial gains that will follow its adoption.

Another recommendation in its favor is that its general adoption by Bureau members may be the means of educating and gradually leading us into a more extended use of the varied phases of co-operation, than which no modern movement holds out promise of greater benefit to producer and consumer alike.

#### SUBJECT REFERRED TO BRANCHES.

Mr. H. C. Williams (MacGillivray) suggested that there was room for the establishment of a co-operative malting plant.

Mr. J. Malcolm (Wallaroo) mentioned the success which had attended co-operation in his district.

The Chairman (Mr. G. R. Laffer, M.P.) said fruitgrowers in this State had combined and erected a plant for the manufacture of jam,

and by so doing had greatly improved their marketing conditions. The export trade in dried fruit depended entirely on the co-operation of the growers. He suggested that the matter might be referred back to the Branches for discussion, the delegates to come prepared to further discuss the subject at the next Congress.

A motion to this effect was subsequently passed.

### HORSE-BREEDING SOCIETIES.

Mr. A. D. McDonald read the following paper on "Horse-breeding Societies":—

In this paper the need of improvement in our draught stock will be taken as conceded, and the paper will be limited to a consideration of horse-breeding societies as a means to that end. It should be recognised that farmers cannot successfully compete with holders of large blocks of northern country in the production of horses of a value of £20 or under at 3 and 4 years old. Also that such horses are not the class best suited for work on the farm. On the other hand northern stations do not produce the better class of draught for which there is a consistent demand.

The first step towards an improvement must be the replacement of stallions of a four-year-old value of less than £150 by horses of double their value. There are scores in South Australia that are not worth more than half the amount named.

I believe it is generally held by competent breeders that mating a £600 stallion with a common mare, in the majority of instances, is not justified by the quality of the progeny thus secured. The better course is to first use a medium priced horse and gradually to raise the standard of the stallion as the quality of the mares is improved.

The business of owners of stallions is to cater for the present demand. They claim that a horse which can be put out at 50s. or less pays the owner best. He has a much easier row to hoe than if he procured a better horse and raised his price to 70s. The position is much the same as in the wheat trade; it does not appear to be anybody's business to stand firm for a higher standard, with the result in both cases that those in its favor are helpless against those who are not.

It is here that the need and opening for organisation occurs. By organisation breeders can exert an influence which is beyond the power of the individual. The objects would be first to bring pressure on stallion owners to purchase better stock, and then to organise rounds for the horses so purchased. They can fix their own standard and choose for their district the horse that conforms to it. Their weight would be against the cheap horse, and should be supported, if necessary, by more stringent regulations in respect to registration and soundness.

### ORGANISING A SOCIETY.

The publication of a scheme by Professor Lowrie to improve the breed of horses by the formation of horse-breeding societies first brought the matter before our Branch of the Bureau during 1912. We asked the Burra Branch to appoint two members to meet two of our own with a view to formulating a scheme to be placed before the farmers of the district. A draft set of rules was drawn up, the district was canvassed for support, and a meeting of horsebreeders was called. That meeting agreed to form a society, adopted the draft rules with slight alterations, appointed office bearers and committee, and gave us enough promises of support to enable us to advertise for a stallion for the season. The rules are as follows :—

#### CONSTITUTION AND RULES OF THE BURRA WESTERN DISTRICT HORSE BREEDING SOCIETY.

President, Mr. J. H. Rogers ; Hon. Secretary, Mr. A. D. McDonald, Koorunga P.O. ; Committee, Messrs. Scholz, T. H. Bailey, J. M. McDonald, W. H. Field, and P. Cornwall.

##### *Name.*

1. The name of the society shall be "The Burra Western District Horse-Breeding Society."

##### *Objects.*

2. The objects of the society are (a) the improvement of the breed of horses in the district, by obtaining the use of suitable stallions to travel the district ; and (b) to establish a fund for the purpose mentioned.

##### *When Constituted.*

3. The society shall be considered constituted when 18 members have been enrolled.

##### *Rules.*

1. The honorary office bearers of the society shall consist of a president and a treasurer (who may be elected from the committee).

2. An honorary secretary (who may be a member of the committee) shall be appointed by the committee from time to time. He shall carry out all directions given and keep all necessary records.

##### *Committee.*

3. The business of the society shall be managed by a committee consisting of seven members, including the chairman, who shall be elected annually from the members. The committee shall elect the chairman.

4. All meetings of the committee shall be called by notice from the secretary. The president may call a meeting at any time. At all meetings five shall form a quorum, and in the event of there not being a quorum at any meeting, those present may adjourn the meeting until a day to be by them fixed.

5. The committee may fill any vacancy on the committee between annual meetings.

##### *Annual and Special Meetings.*

6. The annual meeting of members of the society shall be held in the month of June. At such meeting only those members who have paid their subscriptions shall be eligible to take part.

7. On receiving a requisition from not less than 10 members setting forth the object of such meeting, the secretary shall, by circular, call a special meeting to be held within seven days of the receipt of such requisition, and such meeting shall only have power to transact and deal with the business set forth in such requisition.

##### *Membership.*

8. The members of the society shall be limited to persons who are the owners of draught brood mares, to be used for breeding draught horses.

9. The membership fee shall be 10s. paid annually in advance.

##### *Banking Account.*

10. The secretary shall open an account with either the Savings Bank or some other bank in the name of the society, such account to be operated by the secretary and treasurer conjointly, and all moneys shall, as far practicable, be paid by cheque.

*Dissolution.*

11. In case it may be deemed desirable at any time to dissolve the society a special meeting of members may be called for the purpose, and if it is then decided by a majority to dissolve the society, the same shall thereupon be dissolved, and the affairs thereof be wound up accordingly in such manner as such meeting shall direct.

*Nomination of Mares.*

12. Any member may nominate one or more draught mares for service, and shall pay to the secretary at time of nomination the sum of £4 10s. for each mare so nominated.

13. In the event of the number of mares so nominated exceeding 75 in any season the committee may decide the nominations to be accepted, or may delegate such duty to a Government veterinary surgeon. In all such cases the nomination fees in respect of mares rejected shall be refunded.

*Selection of a Stallion.*

14. The committee may, when 50 draught mares have been nominated, select a stallion for the season. Such stallion shall be not less than four years of age, shall be certified by a Government veterinary surgeon to be sound, and shall be a horse of good quality and breeding.

15. The fees to be offered for the service of such stallion shall be £1 10s. per mare served, payable at the end of the season, and a further sum as premium, viz., £3 for each foal, left payable on July 1st of the year following.

16. The number of mares to be served by the stallion in any one season shall not exceed 75, and it shall be agreed with the owner of the stallion to limit such stallion to the mares nominated by the society for the season. Such season shall extend to 15 weeks.

17. The owner of the stallion selected shall be required to agree to travel such stallion in the district and follow an itinerary satisfactory to the society, and such owner shall agree to pay all expenses in connection with the travelling of such stallion for the season.

*General.*

18. Owners of mares served by the stallion are required to produce them at their stables between June 20th and July 1st of the year following service for inspection by the committee. Mares not produced will be considered to be in foal. If necessary, mares will be again inspected during August.

19. The sum of £3 per mare will be refunded to the owners of mares which do not prove in foal.

20. The committee cannot incur any expenditure beyond the amount of subscriptions received from members.

These rules were adapted from the model set approved by the Minister of Agriculture in place of Professor Lowrie's first scheme. The principal alterations are—the number of mares was reduced from 84 to 75; the payments were altered from £4 4s., with a possible return of £1 if mare did not prove in foal, to £4 10s., with a return of £3 if no foal were left.\* The regulations relating to subsidies were left out altogether.

After a year's trial the majority of our members were opposed to any alteration. The rule requiring payment in advance was not strictly enforced, and the season had ended before all amounts were paid. The principle, however, is good, and payments will be more promptly made in future as a result of the year's experience.

At our last general meeting it was resolved to pay Savings Bank interest for the full time the money was in the bank. The general expenses of the society for last year worked out at 3s. per member for 35 members. This may be taken as a guide for other societies. Selectors' expenses are not included, as in our case the selectors made no charge. The balance of our members' subscriptions was voted to a reserve fund.

## GOVERNMENT SUBSIDY NOT APPLIED FOR.

The question of Government subsidy was discussed when our rules were drawn up. We did not attempt to comply with the conditions for the following reasons :—The number of mares required, viz., 76, and the fees payable, £4 4s., taken together were more than we were likely to secure on an average sized round, and there was the feeling that we could and should do without it in any case. After a year's experience of the work I am of opinion that a society would be courting failure by attempting to comply with those conditions. A society is required to have 76 mares nominated, and the fees, £4 4s. per mare, together with members' subscriptions, banked before it can claim a subsidy and advertise for a stallion. That means not later than July 1st in any year. The condition places the two-thirds of the members who would pay promptly at the mercy of those who would not. The scheme offers no encouragement to the large area where particularly big horses are not needed but where there is much room for improvement. The amounts offered as subsidies—£100 to £130—are not needed in the only districts likely to claim them.

The principal item of expenditure in a society will be selectors' travelling expenses, and when selectors have much travelling this will prove a rather heavy drain on the funds. A Government subsidy with a maximum of, say, £25 towards travelling expenses actually incurred would be a considerable help to young societies, and perhaps turn the scale between success and failure ; or alternatively the department might arrange to place the services of two or three recognised judges at the disposal of societies.

In conclusion, horse-breeding societies require for their successful working the same spirit of loyalty among members that is necessary in any co-operative movement. If breeders recognise the good that these societies can do, and select strong committees to arrange matters, and stand by them, the movement can be made a success.

## THE DISCUSSION.

Mr. H. H. Davie (Mount Remarkable) said his Branch had considered the question of horse-breeding societies and also the prospectus which had been issued by Professor Lowrie, but they did not see how the scheme could be worked. One objection was that the tendency would be to clear out the low-priced horse, which, however, produced very good stock. Then another objection was that there was a better chance of getting a foal from an animal not too fully worked.

Mr. W. J. Colebatch said the subject of horse-breeding was one in which he took a keen interest, and he certainly thought the paper they had just heard, and which had been written by one of his old college mates, was one of the most thoughtful read before Congress.

Whilst there were many good points in Professor Lowrie's scheme, they must admit that the scheme outlined that day was an improvement. The great objection he had heard taken to co-operative horse-breeding societies was that they asked the farmer to nominate his mare to a horse he had not seen. The last speaker had stated that one objection his Branch had to the original scheme was that the low-priced horse would be forced out of competition. That might be so, and it might be that there were certain districts not sufficiently advanced for a scheme like the one placed before them. But there were many districts which could well take up some such scheme, and he was sure that the result of using a well-selected stallion would be the general improvement of the horse stock in the district. He hoped the particulars placed before them by Mr. McDonald would lead other districts to take the matter up.

Mr. F. E. Place (Veterinary Lecturer) hoped the delegates attending Congress would read Mr. McDonald's paper carefully three or four times, and then set about doing something in the direction of forming horse-breeding societies in their respective districts.

Mr. A. L. McEwin (Blyth) said he never heard of horse-breeding societies without wondering what kind of horse was wanted. If any one could answer that question satisfactorily he knew more than he (the speaker) did. He had been breeding for 30 years, and now had seventy horses, and though, as they knew, some one had lately been purchasing horses, he did not have one they wanted. They were all too big. The horse that was doing the work in South Australia to-day was the mongrel—the horse with a strain of the roadster in him. He saw no reason for horse-breeding societies, and did not see how the farmer would gain anything by them. The lines on which the Burra Society was being worked seemed very good, but the fault was that the other fellow chose the horse.

Mr. A. V. Thompson (Keith) said a number of farmers had mares for which it was not worth paying a service fee of £4 10s. A fee of £2 was quite enough, and he had often noticed that a low-priced stallion left more foals than a high-priced one. The settlers outback who had four or five mares could not afford to pay a service fee of £4 10s. for each mare. He thought the rules regarding the registration of stallions were sufficient protection.

Mr. McDonald, in reply, said that he would not try to convince those who held the opinion that a mongrel was just as good to breed from as a pure-bred. Regarding the argument that in the case of horse-breeding societies the farmers had no choice of the stallion, he pointed out that they had no choice at present.

### **EVENING SESSION.**

The evening session was attended by a large number of delegates and visitors. Mr. F. Coleman presided.

### **ROSEWORTHY COLLEGE.**

#### **REVIEW OF SOME WORK DONE IN LAST DECADE.**

##### **INTRODUCTORY.**

The Director of Agriculture (Professor Perkins) read the following paper, entitled "A Review of Some of the Work Done at the Roseworthy Agricultural College in the Last Decade":—

I must confess that, in past years, as congress time has approached, I have always found it difficult to fix upon a suitable subject to deal with. I must add now that the very recent change in my official position has added considerably to my difficulties in this direction. It will be agreed, I suppose, that my long isolation at the Roseworthy Agricultural College, shuts me out, for the present, at all events, from any discussion of earlier departmental work. I might be expected, perhaps, to sketch out a plan for future operations; I hope, however, that I shall be excused from doing so. I fancy that you will find that, in this connection, deeds are preferable to promises, and that the evidence of work accomplished will speak more eloquently than the most brilliant exposition of work that is yet to be done. I have thought, therefore, that I could not perhaps do better than place before you, in brief summary, some of the more important lines of work that have occupied us at Roseworthy during the past 10 years.

In taking up this subject, I must confess to two objects: in the first place, I believe that much of the work done by us in the past 10 years is of direct value to the agricultural community, and, as such, will bear repetition and emphasis; and, secondly, I hope to show that, apart altogether from its normal activities as a teaching institution, the Roseworthy Agricultural College has fully justified its existence during the past 10 years. I believe that I am right in stating that this institution has earned the esteem of the thinking portion of the agricultural community; I recognise, however, that its power for good is strictly limited by the numbers who have faith in it, and I entertain the hope that this address may have the effect of gaining to it the approval of many who may, hitherto, have held aloof.

## IMPROVEMENT OF WHEATS AND BARLEYS BY SELECTION.

The work of improving wheats and barleys by systematic selection was first taken in hand in 1904, and has been continued regularly from year to year ever since. In a paper published in 1908 I explained in detail the principles on which we have worked; and briefly, the position may be summarised as follows. Other things being equal, the yield per acre of a cereal crop is dependent on the quantity of grain carried by the average plant of the field under consideration, and the latter on the contents of the average ear of corn. In this selection work, therefore, we have directed attention, first to individual plants, and secondly to the ears which they bear. Strong, well-grown plants, which have successfully resisted the weather, have alone been retained; from these plants the best ears have been systematically picked out. In selecting the latter, attention has been directed to several points, among which the principal are—(1) Ability to hold grain firmly, (2) Absence or minimum of barren or empty spikelets, (3) Length of ear, (4) Number of spikelets, (5) Average number of grams in each spikelet.

In this connection, it may be stated that all the College selected strains of cereals are strictly pedigreed. Thus, a suitable ear from a suitable plant is selected and receives a number or distinguishing name. The grain of this ear is graded with a hand grader, and the best developed grains alone are then sown out in hand plots, i.e., they are dibbled out in rows, each individual grain being spaced a link apart. In this way, the grains of individual ears is always kept distinct from that of other ears of the same variety; and, should individual variations arise—as occasionally happens—they can always be traced to their source of origin, and retained or discarded, as circumstances appear to suggest.

At harvest time, the hand plots are carefully gone over, and the best ears are again picked out from the best plants, their origin and pedigree being carefully noted at the time. These ears supply grain for the hand plots of the following season. Subsequently, a stripper is run over what remains of the rows of selected plants, and the grain harvested supplies seed for what we have termed seed plots, generally one to two acres in area; and these, in their turn supply us with ordinary farm seed in the season that follows.

In the case of many varieties of wheats and barleys, this systematic selection has now extended over 10 years; others we have had in hand for shorter periods of time. We have always thought it well to indicate the length of their pedigree in the following way. In the present season, for example, we have in selection plots what we term King's Early of the 10th Selection. This means that the

wheat in question has been grown for 10 years in succession in selection plots, and represents, therefore, 10 successive generations of the best ears from the best plants of this special variety. All breeders, whether of plants or livestock, will agree that systematic selection conducted on these lines must ultimately have the effect of influencing favorably the yield of all varieties so handled; and, indeed, we already have ample evidence that such has been the case with those varieties that received our earliest attentions. On the College Farm itself, although new varieties are constantly being tested, we have not come across new varieties consistently superior to the College selected strains. It was with much pleasure, too, that I noticed recently, that in the Balaklava Wheat Competition, extending over three years, the first and second prizes went to two college wheats—King's White, and College Eclipse. Quite recently, too, College Eclipse headed the yields on the Victorian Government farms. Many farmers, too, who have secured seed from the institution, have had reason to be satisfied with their results.

Before leaving this subject, I wish to say a word on another method of selection sometimes recommended, and that is "roguing," or picking out inferior plants, instead of breeding systematically from the best. Whilst I quite admit that selection of this kind is better than none, I must state very emphatically that its value, on the whole, is very small. However small a plot of wheat may be, I defy anybody to go through it and "rogue" out all the poor or unsatisfactory plants. Moreover, advantages of pedigree are lost, since it is not only unsatisfactory plants that should be "rogued out," but also the good ones of the same strain. Selection, to my mind, can be effective only when accompanied by strict pedigree

#### NEW VARIETIES OF WHEAT.

We have not, however, confined ourselves to the improvement of existing varieties we have also endeavored to create new varieties by means of judicious crosses; and, at the present time, we have in hand quite a number of what appear to be very promising new wheats. New varieties, however, cannot be brought into existence and permanently fixed in the course of a single season. Work of this kind generally extends over three to five years, and must subsequently be completed by field tests on a large scale. All that can be said on this subject at the present moment is that, after a very severe weeding out process, 14 or 15 new varieties of wheat are being grown on a fairly large scale on the College Farm in the present season; we hope that some, at all events, may ultimately find their way on farms that are similarly situated.

### LIVESTOCK AND SOUTH AUSTRALIAN FARMING.

In past times, economic conditions have been such that South Australian farming could be described, with absolute truth, as wheat farming, and that such should have been the case can hardly now be made a matter of reproach. There is no type of farming better adapted to pioneering work than wheat farming, pure and simple. We all recognise, however, that taken by itself, wheat farming can represent no more than an early phase in the development of our rural industries.

Soon—one might almost say now—livestock operations must work hand in hand with wheatgrowing, and so bring about greater variation and greater interest in farming operations. I may say that, from the first day I took charge of the College Farm, I endeavored to concentrate my attention on what appeared to me to be an unavoidable change in our farming practice. In earlier days, the College Farm, reflecting current practice elsewhere, carried but a limited number of livestock: hence, having everything to learn, I made it my chief aim during 10 years to discover what was the maximum livestock carrying capacity of the College Farm. With this subject, I dealt at considerable length last year; and I do not wish to-day to do more than point to what may be termed the chief conclusions of 10 years' experience. My main conclusion is this: on a farm of this type, wholly arable, with two-fifths of its area yearly under cereals, two-fifths treated as bare fallow, and one-fifth utilised for pasture purposes, the average sheep-carrying capacity would be represented by about one sheep to the acre over the whole farm area. I know that, in earlier days, when I stated this to be my conviction, I was laughed at for my pains; I have the satisfaction of knowing to-day that 10 years' patient work has demonstrated the fact beyond possible dispute. This, I submit, is a fact that must count for much in the future development of our rural industries.

### FORAGE CROPS AND HAND FEEDING.

This leads me to the requirements of a farm flock, as distinct from those of a station flock. When I stated that, under the conditions of cropping indicated, an average Lower North farm can carry a sheep to the acre on the whole area, I did not have in view the unavoidable practice of the station owner, but what should be the practice of the farmer, who keeps sheep as well as grows wheat. Now the station owner very naturally judges of the carrying capacity of his run by the numbers that he can comfortably support in the worst period of the year; and experience teaches him that, if he exceeds this limit, he is exposed to very serious losses.

The station owner, however, is dependent exclusively on the herbage that springs spontaneously in his paddocks, and inability to adopt maximum stocking means that, at certain times of the year, much of this herbage must go to waste. The resources of the farmer, on the other hand, are, or at least should be, otherwise greater. If the farmer limits his numbers to the actual carrying capacity at the worst time of the year of the few fields he leaves out of cultivation, the number of sheep he will carry will be so small as barely to affect his annual receipts. If a station owner is overstocked, his sheep must lose condition, the fleeces deteriorate, the lambs may perish, and the whole flock may starve. On a properly conducted farm, apart from very exceptional seasons, I am of opinion that sheep need never be allowed to get below good store condition. This means that, over and above what grazing natural pasture will supply, the farmer should have at command other sources of feed, to which the flock can be given access whenever occasion arises. This again implies the raising of suitable forage crops on the one hand and the judicious use of hand feeding if need be.

It must be admitted that, hitherto, we have found the number of forage crops adapted to Lower North conditions to be very limited, and on the whole their success and usefulness is, as a rule, dependent on an early start and good autumn rains, both of which have unfortunately been denied us of late. In our experience, the forage crops most to be recommended are rape, kale, pease, lucerne, mustard, and sorghum. All of them fit in, as a rule, tolerably well with ordinary wheat farming, and help to keep the flock going when natural pasture fields are recovering from heavy grazing.

But, in many a season, intervals will arise when neither forage crop nor natural pasture afford sufficient grazing to a farm flock: then is the time to fall back on a short period of hand feeding, which, as a rule, will not extend beyond six to eight weeks. The actual cost of this hand feeding is never very great, and can always be provided from the supplies of the farm itself. According to the size of the sheep, 2lb. to 4lb. of chaff a head daily will suffice; or a pound or two of grain, barley, oats, or wheat will be ample, not much more than  $\frac{1}{2}$ d. to 1d. a head a day. Unquestionably hand feeding of this kind must, even on a farm, prove expensive, if made to extend over the whole year; when referred to a few weeks, however, it is a very small matter. The essential is, however, that hand feeding should not be delayed unduly: the flock should be fed before they have completely exhausted what grazing is available, and, at all events, before they begin to show signs of falling off in condition. In our work at Roseworthy, although in the majority of seasons we have been able to do without it, we have never hesi-

tated to fall back on hand feeding, when seasonal conditions rendered it necessary: we have thought it no more an economic crime to feed wheat to sheep than to feed it to pigs.

#### THE FARMER'S FLOCK.

I have always held the opinion that it is safer for the South Australian farmer to rear fat lambs for market than to purchase stores with the object of fattening them. The one appears to me a legitimate farming operation, whilst the other, with our fluctuating markets, is far too speculative in character to be generally commendable. I do not deny, however, that if we succeed in establishing a definite overseas trade in mutton, that we may then count on fairly steady markets, and that topping up stores will then prove a perfectly legitimate operation. At the College, however, hitherto attention has been exclusively concentrated on the fat lamb flock. After a number of trials, it would appear to us that the most profitable dam of fat lambs is, under our conditions, the half-bred Leicester, or the half-bred Romney Marsh ewe, and the best sire the South Down ram. Details concerning our tests have been published elsewhere. I need, therefore, here do no more than draw attention to our final conclusions.

#### FARMING ROTATIONS.

We have given considerable attention to the question of farm rotations suitable to local conditions: questions of this kind, however, which involve both economic and climatic considerations do not, as a rule, admit of being settled satisfactorily in a period of 10 years. We may claim, however, to have shown very definitely the advantages of associating six-row barley with wheat, particularly in the lighter lands of the district: in this connection, either one or the other of the following two rotations may be recommended:—

|                       |             | B.          |
|-----------------------|-------------|-------------|
| First year . . . . .  | Bare fallow | Bare fallow |
| Second year . . . . . | Wheat       | Wheat       |
| Third year . . . . .  | Barley      | Barley      |
| Fourth year . . . . . | Bare fallow | Pasture     |
| Fifth year . . . . .  | Wheat       | Bare fallow |
|                       | &c., &c.    | &c., &c.    |

The College returns show very clearly that these two rotations are infinitely more profitable than the two local alternatives, bare fallow—wheat or bare fallow—wheat—pasture. I am quite aware that numerous objections are raised to the introduction of barley on a wheat farm. To my mind, however, there is only one objection that is worthy of serious consideration, and that is the fluctuations in price to which barley is subject, when compared with

wheat. The position, of course, is that the price of wheat is regulated by the steadier requirements of the world's trade, while the price of barley is subject exclusively to local demand, and is dependent on the abundance or otherwise of the harvest. This, no doubt, is a difficulty; it can, however, easily be overcome by the establishment of an overseas export trade. I showed, in a paper read before Congress in 1913, that the average imports of barley into Great Britain were represented annually by close on 46 million bushels; and it is only a question, therefore, of capturing portion of this trade to find barley as stable in our markets as wheat. Let it not be forgotten, too, that if we take acre-yields into consideration, barley is one of the cheapest concentrated foodstuffs that can be grown; and if we are not satisfied with local prices, we can always convert it at a profit into pork or mutton, or feed it to horses instead of oats.

#### MANURES.

Experiments with manures of various kinds generally appeal to the imagination of an agricultural community, very largely, perhaps, because of the visions of enhanced yields which they conjure up. And I suppose it must be recognised that the Roseworthy Agricultural College owes much of its earlier reputation to the helping hand it was able to lend in this direction to struggling farmers, whose pioneering practices had exhausted the virgin fertility of the soil, and who were at a loss how to handle so-called "wheat-sick land." Professor Custance, the first Principal of the institution, was, I believe, the first to draw attention to the effectiveness of phosphatic manures on South Australian soils; he was, however, in advance of the times, and the work of emphasising the fact, driving it home and popularising it in an incredibly short space of time was left to his successor, Professor Lowrie. During the past 10 years, work has been continued in this direction upon systematic lines; and I propose drawing your attention to some of the facts we have been able to establish.

#### PHOSPHATIC MANURES.

We are able to confirm the great value of soluble phosphatic manures on soils of the Roseworthy type, particularly in dry seasons. I have not to-day the leisure to elaborate the point, but I am in a position to maintain very definitely, that in our district, phosphatic manures, which are indispensable to a good crop in normal and dry years, exercise far less influence on yields in wet years, and particularly in late seasons. I shall give one example to illustrate this point. Season 1909 was a typically late wet year, in which plots dressed with 2cwts. of superphosphate yielded

28bush. 1lb. to the acre, and no-manure plots 23bush. 32lb.: this represents a gain in yield to the credit of the manure of 4bush. 29lb., or slightly in excess of 19 per cent. Season 1912, on the other hand, was a low rainfall year, in which plots dressed with 2cwts. of super. per acre yielded 23bush. 32lb., and no-manure plots 12bush. 2lbs.: a gain therefore of 8bush. 32lbs., or close on 71 per cent. above the unmanured crop. The explanation appears to me simple enough: in a general way a dressing of superphosphate appears to stimulate a wheat crop, particularly in the early stages of its growth, with the result that it is always more forward and ripens earlier than an unmanured crop. Hence if the season is normal and comparatively early, the manured crop ripens satisfactorily, whilst the later unmanured crop is checked in its development, and the yield is correspondingly lighter. In late, wet years, on the other hand, the unmanured crop has time to catch up the manured one, and, at times, yields far more heavily than could possibly have been anticipated earlier in the year.

There has been much controversy as to the most profitable dressing of superphosphate to be used for wheat; and we have heard advocates of light dressings and advocates of heavy dressings. It is no secret, I suppose, that I have always been an advocate of what are taken here to be heavy dressings; and my views have always rested on the results of our experience. It is perfectly true, of course, that the difference in yield of wheat dressed with 2cwts. of superphosphate on the one hand, and wheat dressed with 1cwt. on the other, is not very great: about  $1\frac{1}{4}$ bush. to  $1\frac{1}{2}$ bush. of grain is our experience, or  $1\frac{1}{4}$ cwts. to  $1\frac{1}{2}$ cwts. of hay. The improved yield may be taken just about to pay for the extra cwt. of manure, and at times to leave a small margin of profit. As a rule, however, we have found no appreciable advantage in making use of dressings of superphosphate in excess of 2cwts. to the acre.

I have often had occasion to point out, however, that increased grain yields is not the only advantage that attaches to the use of heavy dressings of superphosphate on our farms. Everybody today recognises that the use of superphosphates, even in light dressings, has had the effect of transforming the grazing character of fields temporarily left out of cultivation. It may be stated without hesitation that we owe the universal spread of the so-called "native clovers" or trefoils to the use of superphosphate. On the College Farm, and particularly on the College Experimental Plots, we can show very clearly that the grazing capacity of land is practically proportional to the dressings of superphosphate applied to the cereal crops. And I have no hesitation in saying that, so great is the improvement of our pastures in this direction that even if

the wheat crop itself does not pay for the superphosphate used, we shall be amply compensated for it by the higher sheep-carrying capacity of the land when left out of cultivation. I must add that this improvement of the pastures is not a sudden growth: no doubt, the fields respond from the first, even to light dressings; but improvement which can be measured almost in sheep to the acre comes only with time and repeated heavy dressings. On the College Farm, for example, we have had occasion to notice over and over again, how much greater is the sheep-carrying capacity of the oft-manured fields of the old, original farm than that of the more recently purchased fields. I may summarise the position, therefore, with the statement that the College results show that it pays both directly and indirectly to make use of 2cwt. dressings of superphosphate to the acre for cereal crops. I am aware that it is sometimes objected to comparatively heavy dressings of superphosphate that they lead to the blighting off of the crop. This is a point to which I have given careful attention, and I can assert most emphatically that such is not the case. This blighting off is usually the natural consequence of special climatic conditions, and whilst it is certainly favored by the rank, soft growth resulting from the use of nitrogenous manures, such as farmyard manure, I have never observed the hardy, healthy crops treated with superphosphate more liable to blighting off than neighboring unmanured plots: I should have no difficulty in giving convincing illustrations of this fact, but must confine myself to-day to simple affirmation of what I believe to be true.

#### BASIC SLAG.

It is a matter of common knowledge that we owe the spread of phosphatic manures in South Australia to the use of water-soluble superphosphate. In Europe, however, basic slag has proved a formidable competitor to superphosphate, over which it has had the advantages of lower sale prices, both per cwt. and per unit of total phosphate. Thus the June "Mark Lane Express" quotes 2s. for the unit of water-soluble phosphate in superphosphate, representing a value of £3 14s. per ton for 36/38 per cent. superphosphate, and 1s. 3d. for the unit of total phosphates in basic slag, representing a value of £2 3s. 9d. per ton for 35 per cent. basic slag. Curiously enough, however, basic slag has been quoted latterly on local markets at higher rates than superphosphate; this anomaly may be explained perhaps on the grounds of limited demand, in the face of doubtful success under local conditions. It may be remarked, however, that to put up the price of a commodity is not the best way to extend its use.

At Roseworthy, we have conducted basic slag tests in wheat in comparison with no-manure and superphosphate plots. A comparison of the means of eight years shows an improvement over the no-manure plot of 36 per cent. for a dressing of 3cwts. of basic slag (20 per cent. citrate soluble phosphate, and 15 per cent. acid soluble phosphate); and an improvement of 27 per cent. for a dressing of 2cwts. of the same manure. Over the same period, however, there was an improvement of 46 per cent. over the no-manure plot in the case of wheat dressed with 2cwts. of 36/38 per cent. superphosphate.

It would appear, therefore, that, under Roseworthy conditions of climate and soil, superphosphate, besides being cheaper, is superior in its effects to basic slag. It should be added, however, that, relatively to the earlier seasons, basic slag has, within recent years, shown marked improvement in its influence on our crops. It is to be assumed, perhaps, that as the citrate soluble phosphate accumulates in our soil, it tends, in the course of time, to become more readily available to our crops.

#### NITRATES.

Nitrate of soda is a form of manure that has acquired an immense popularity under relatively moist conditions of climate. Lawes and Gilbert, for example, in the course of a long series of experiments were able to show that the yield of wheat at Rothamstead was almost proportional to the amount of nitrogen brought to the soil. There is no doubt that our conditions are very different, and, as a consequence, we find nitrate of soda used very sparingly, if at all, by South Australian farmers. This manure has been tested systematically on the Roseworthy Agricultural College Farm for nine successive seasons, and I propose drawing attention to some of our results.

We find, in the first place, that a plot dressed with 2cwts. of superphosphate and 1 cwt. of nitrate of soda to the acre, yielded, on the average, 3bush, of wheat or 5cwts. of hay per acre more than a neighboring plot dressed only with 2cwts. of superphosphate. The gross value of these increases would be respectively 10s. 6d. and 9s. an acre, that is, less than the local cost of 1cwt. of nitrate of soda, 14s.

It might be imagined, of course, that a lighter dressing of nitrate of soda would have proved more remunerative. We have, however, tested both  $\frac{1}{2}$ cwt. and  $\frac{1}{4}$ cwt. dressings; the former has given fairly satisfactory results on light soils in wet years, whilst the lighter dressing has had no perceptible influence on the crops. We have

also raised the quantity of superphosphate, whilst maintaining the nitrate of soda at 1cwt. This experiment, however, has not, as yet, extended over a sufficiently great number of years to be worth quoting.

I am inclined to conclude that, in the way of general practice, farmers whose rainfall does not exceed 20in., will have no cause to make use of costly nitrate of soda. There are times, however—and we have had experience of them—when crops raised on light sandy land will benefit very considerably from a spring top-dressing of nitrate of soda, after an abnormally wet winter: I recommend  $\frac{1}{2}$ cwt. dressing for the purpose. It is quite possible, however, that nitrate of soda or some other form of nitrogenous manure may prove invaluable on the land of some of our wetter districts.

#### POTASSIC MANURES.

We have tested both the sulphate and the muriate of potash, alone and in conjunction with superphosphate. The results may be stated to have been absolutely negative, except, perhaps, in the case of very light lands after wet winters. Generally speaking, I can see no reason to recommend the use of potassic manures on either our heavier types of soil or on the loams of moderate consistency. It is possible, however, that like nitrates, they may prove useful in the lighter lands of our wetter districts.

#### FARMYARD MANURE.

I am quite aware that the average farmer—to make use of a colloquialism—has no time for farmyard manure. Many, I believe, would willingly burn it, like their stubbles, if they could do so conveniently and expeditiously. And yet this is the oldest form of manure in use in the world; and perhaps, if we take area into consideration, still the most extensively used manure to-day. No doubt, there are good reasons for the wheat farmer's antipathy to farmyard manure. It involves him in costly and laborious hand manipulations; it causes his crops to lodge; it causes the crops to blight; and when badly prepared, is an admirable agent for spreading weeds. And yet, surely, gentlemen, it has its virtues, or else we should not find it so highly valued by others; and, above all, it is there, and it must be disposed of somehow, and it is our business to see that it is turned to best advantage. Those who object to farmyard manure on principle, are surely inconsistent, if, at the same time, they look to grazing livestock to improve the texture of their land by restoring to it organic matter, which bare fallowing operations are systematically burning up and destroying.

In the Permanent Experiment Field, we have had a pair of plots alternately under wheat and bare fallow, dressed regularly in the bare fallow year with farmyard manure at the rate of 14 tons to the acre ever since 1905, and more recently additional plots dressed with both farmyard manure and varying combinations of mineral manures.

The farmyard manure alone cannot be said to have given us wholly satisfactory results. In the course of eight seasons, the grain yield was about  $4\frac{1}{2}$  bush. better than that of unmanured wheat; slightly better than the yield of wheat dressed with 2cwts. of basic slag; and about  $2\frac{1}{2}$  bush. less than that of wheat dressed with 2cwts. of superphosphates.

But nobody would recommend using farmyard manure alone for cereals; and—as has already been stated—in our more recent plots, we have associated it with superphosphate, and with sulphate of potash; but because these plots do not extent further back than two seasons, both of which were rather abnormal, I shall content myself with saying that we can show that farmyard manure alone will lead to increased yields; and that I believe that, in combination with superphosphate, it will give the highest yields that our soils and climate admit of.

I admit the force of the objections made by the wheatgrower to farmyard manure; but I also believe that, in other directions, its virtues make ample compensation for them. That crops will tend to lodging and blighting, when heavily dressed with farmyard manure, is perfectly true; but so will crops raised on a sheep camp, or on land very heavily stocked. And the remedy appears to me simple enough; use this valuable substance sparingly; if 14 tons to the acre is too heavy a dressing, halve it; or, if you grow summer fallow crops, such as maize and sorghum, make a point of putting the farmyard manure on the land that is to carry these crops. Not only will these crops benefit greatly by the dressing, but they will also remove from it some of its tendency to push the wheat crop to soft, sappy straw growth. I must admit that, in certain circumstances, I have come to look upon the burning of stubbles as unavoidable; but the deliberate waste of farmyard manure is nothing short of a grievous economic sin.

#### METHODS OF CULTIVATION.

One might almost say that methods of cultivation for wheat growing have already been practically "standardised" in the Lower North districts. The so-called "Dry Farming" methods of the

arid portions of North America, are after all no more than local modifications of our own well-tried practice, and are of value to us only so long as they keep within the narrow way blazed out for us by many years of dearly bought experience. Land which is to carry wheat we break up as early in the winter as circumstances permit of; we work it down in the spring months to the requisite degree of tilth; we consolidate the sed bed; we encourage the germination of weeds and keep them from running to seed with tillage implements and sheep; and finally, we sow the seed, nine or ten months after the first ploughing, as soon as weather conditions appear propitious to our purpose. It may be asked, in the circumstances, in what direction further experimental work is likely to lead to any improvement in these cultivation methods of ours. To an objection of this kind, there are, I think, two replies that can be made: Firstly, if we admit that long personal experience has brought the cultivation methods of many of our best farmers very close to perfection, this experience is theirs alone, and that perhaps of their immediate neighbors; the State, however, must concern itself with the needs of those who are not perhaps so favorably situated, and particularly of those who are taking up farming with everything to learn. Secondly, although I have certainly taken upon myself to describe the cultivation methods of the Lower North as being more or less "standarised," it must be admitted that even on this subject differences of opinion exist on quite a number of points of interest. And it is chiefly in view of this, that some four years ago I established a series of plots to test the value of various practices in handling bare fallow; the results hitherto registered are, however, too limited in number and character to carry with them any great weight.

Before making reference to these results, I should like to draw attention to some data we are able to give, which throw out into very clear light the advantages of well-worked bare fallow and good tillage methods. From 1905 to 1907—three successive years—we endeavored to grow wheat continuously year after year, on the same land. We had for the purpose seven plots, variously manured, and covering in the aggregate an area of about 14 acres. In 1908 all these plots were treated as bare fallow, and in 1909 they were again put under wheat. The combined average grain yield of these seven plots is shown below, in tabular form, comparatively with the combined average of nine other plots—aggregating 18 acres in area—which on the whole were not as heavily manured, but were in each year preceded by one year's bare fallow.

TABLE I.

Showing grain yields of land continuously under wheat comparatively with that of wheat preceded by bare fallow.

|         | A.<br>Land continuously<br>under wheat for<br>three (3) years. | B.<br>Land alternatively<br>under wheat and<br>bare fallow. | Difference between<br>A and B. |
|---------|----------------------------------------------------------------|-------------------------------------------------------------|--------------------------------|
| 1904 .. | Bare fallow                                                    | Bare fallow                                                 | —                              |
| 1905 .. | 29bush. 19lbs.                                                 | 30bush. 32lbs.                                              | — 3.98 per cent.               |
| 1906 .. | 9bush. 5lbs.                                                   | 21bush. 0lbs.                                               | —56.74 per cent.               |
| 1907 .. | 3bush. 53lbs.                                                  | 17bush. 3lbs.                                               | —77.22 per cent.               |
| 1908 .. | Bare fallow                                                    | —                                                           | —                              |
| 1909 .. | 35bush. 25lbs.                                                 | 29bush. 10lbs.                                              | + 17.65 per cent.              |

It will be noted that all plots were preceded by bare fallow in 1905, and that in consequence yields were substantially similar. In 1906, however, land preceded by bare fallow was close on 57 per cent. better than land carrying a second crop of wheat; whilst in 1907 land preceded by bare fallow was over 77 per cent. better than land carrying a third crop of wheat. After an interval of one year's bare fallow, however, we find the same land that had previously carried wheat for three years, yielding close on 18 per cent. better than neighboring land alternately under wheat and bare fallow. I do not think that we could wish for a more striking example of the advantages of thorough tillage operations.

Adverting now to our special cultivation plots, of which as yet we have only the results of two harvests, we may note in the first place that early fallow—i.e., land broken in July—has proved itself infinitely superior to late fallow—i.e., land broken after September. We have also found the use of a heavy land roller a distinct advantage, particularly in the case of late fallow. Thorough and frequent tillage, too, has proved superior to occasional working. I freely admit, however, that two seasons' results are not sufficient warrant for any very definite conclusions on the subject.

#### DEPTH OF TILLAGE.

In a sense depth of tillage might be included with cultivation methods; at the College we have given the subject special treatment, because we thought it involved other matters of special importance. In 1910 we set out six pairs of acre plots, which have carried wheat in alternate years ever since, after one year's bare fallow. The depth of ploughing has varied from 2in. to 12in. according to the plots. We have as yet the results of only three seasons, and these, on the whole fairly abnormal ones; hence definite conclusions on the subject would be rather premature. We may note, however, that the heaviest average yields are to the credit of the plots broken

up to depths of 8in. to 12in. I will add that throughout these four seasons the distribution of the moisture in these several plots has been carefully determined, and I trust later on to be able to submit interesting data on this subject.

Beyond supplying our own requirements in the way of cattle feed, we have not done much in the way of irrigation work; and this chiefly because we have been severely handicapped by an inadequate supply of water. A better supply has on various occasions been promised us, and I entertain the hope that my successor may ultimately find himself better situated for experimental work in this direction. I think, however, that I can point to one piece of irrigation work of ours which is likely to be of much advantage to the State; I refer to our demonstrations of the great value of Egyptian clover as an irrigated winter crop. It seems fairly certain that the bulk of our irrigation areas must depend upon dairying for their prosperity; and whilst hitherto, given an adequate water supply, no difficulty has been experienced in keeping up a continuous supply of green forage for cows over the warmer months of the year, the same cannot be said of the winter. How to keep the cows going on green forage during the winter months has, I understand, been one of the problems of our semi-arid irrigation areas. When I was in Egypt, in 1910, I was surprised to find that they had there a rank-growing winter forage, which kept all the livestock of the country in good condition during the four winter months. Now, the climate of Lower Egypt is arid enough, the average annual rainfall varying according to districts from  $\frac{1}{2}$  in. to 6 in.; and it occurred to me that a winter crop that yielded 28 to 30 tons of green stuff to the acre in winter in Egypt should do quite as well on the Murray Swamps, which, to my mind, were more fertile. I accordingly made arrangements to have Berseem seed sent out to South Australia for the purpose. This seed should have been tested on the reclaimed swamp lands in 1911; for various reasons, however, the season was missed. Fortunately, I retained some seed for the College irrigation plots; and the results were so satisfactory that we have continued growing this crop ever since. I can now state, with the results of four seasons before me, that I know of no crop calculated to yield heavier winter growth under Roseworthy conditions than Berseem or Egyptian clover. In 1913 we took from Berseem in five cuts, between June and November, over 36 tons of green stuff; and followed it up immediately on the same land with a summer crop of sorghum, which I estimate to have gone between 25 tons and 30 tons of green stuff to the acre. There are few crops, if any, which under irrigation conditions will yield in the course of a twelve-month 60 to 70 tons of green stuff to the

acre; and this is what may easily be gathered from a combination of Berseem and sorghum.

I shall summarise what experience has taught us to be essential to success with Berseem. Choose by preference a rich, heavy soil; if natural fertility is only moderate, dress heavily with farmyard manure. Sow early, while the soil is still warm; at the end of March, or, at latest, early in April; in these circumstances the seed will germinate in moist soil in three or four days. Sow at the rate of 25lbs. to 30lbs. to the acre; and irrigate sufficiently to keep the young plants in a healthy state of growth over the dry autumn months. The first growth will not be as rapid as subsequent growths. Start cutting as soon as the crop is 15in. to 18in. high; with March sowing this should take place early in May. The crop will yield four or five cuts, according to the character of the season; and under favorable conditions may be reckoned to yield 30 tons to 40 tons of green stuff to the acre. In the same year, as soon as the hot weather sets in, it may be followed immediately by a summer irrigated crop.

Lower Egypt is a country in which, so far as I was able to ascertain, frosts are unknown; and I was curious to note how Berseem would stand our winter frosts. In 1913 the crop had to run the gauntlet of several very frosty mornings; and on one occasion it stood 10 degrees of frost without turning a leaf. Hence I feel that I can confidently recommend Egyptian clover to our irrigationists.

#### WHEATEN HAY.

In both 1911 and 1912 we undertook exhaustive inquiries into the quality and character of wheaten hay cut in various stages of development, completing them with direct digestibility tests on horses. Our results were published in two pamphlets in 1912 and 1914. The main conclusions of these experiments may be summarised as follows:—

1. Maximum yields of hay are gathered in when the wheat crop is cut with grain just about to leave the milky stage, i.e., beginning to take a firm consistency. This will be between three and four weeks after bloom, according to districts and seasons. If the crop is cut earlier or later, yields will be lighter.

2. In the first three weeks after bloom both the ears, on the one hand, and the culms and flag on the other, progressively gain weight, although not in the same proportion. After that period, i.e., when the grain begins to gain firmness, the ears continue to increase in weight, whilst culms and flag, after a short period of

rest, begin to lose weight. Hence late-cut hay is badly balanced hay, in which culms and flag have been drained for the benefit of the ears.

3. Taking the crop as a whole there is an actual loss of dry matter in the last two or three weeks of the development of the wheat crop.

4. The average moisture contents of South Australian wheaten hay is about 10 per cent., varying slightly according to the stages in which it has been cut.

5. The loss of moisture in drying varies from 25 per cent. to 75 per cent., according to the stage of maturity attained to by the crop.

6. In our experiments hay cut at full-bloom time proved more digestible than any hay cut at later periods; and, generally speaking, the maturer the hay the less digestible did it prove.

7. The albumenoid ratio of comparatively green hays, calculated on digested material, is narrower than that of maturer types of hay.

8. Finally, we concluded that there was nothing to be gained, and much to be lost, in putting off the cutting of wheaten hay until the grain enters frankly upon the dough stage. It involves as a rule both a reduction in total yields of hay, and a reduction in quality, represented by a reduced digestibility and a wide albumenoid ratio. Hence, assuming that hay-cutting operations can be completed within a week to 10 days, we were of opinion that these operations should be put in hand not later than a fortnight after full bloom.

#### DEPTH OF SOWING.

Between 1906 and 1909 we carried out a series of experiments with a view to determining the most suitable depth of sowing for various agricultural seeds. The results of these experiments were published in 1912, the chief of which may be summarised as follows:—

**Wheat.**—In sandy land the most suitable depth of sowing is between 1in. and 2in.; and in heavy land never deeper than 1in. In spite of this, we found that in sandy land more than 50 per cent. of the seed sown germinated when placed 6in. deep, and in the case of heavy land when placed 4½in. deep.

**Barley.**—In sandy land the best depth for sowing would appear to vary between 1½in. to 2½in., and in heavy land between 1in. and 1½in.

**Oats.**—In sandy land the most suitable depth would appear to be between  $1\frac{1}{2}$  in. and  $2\frac{1}{2}$  in. Deep sowing does not appear to injure oats in this type of land, two-thirds of the seed sown germinating even from a depth of 6 in. Oats would appear to germinate more slowly than wheat or barley. In heavy land  $1\frac{1}{2}$  in. to 2 in. would appear to be the best depth; although here, again, three-quarters of the seed sown germinated successfully from a depth of  $5\frac{1}{2}$  in.

**Field Beans and Pease.**—Beans and pease were tested in sandy soil only, in which depths of 2 in. to 3 in. appeared most suitable.

**Maize.**—Our tests were restricted to maize raised independently of irrigation. In our conditions of climate, involving as they frequently do hot, dry springs, deep sowing is alone to be recommended for maize. It is difficult to specify any particular depth; as a result of our experiments, however, we suggested 3 in. to 4 in. as suitable depths. The essential is however that the layer of soil receiving the seed should be not only sufficiently moist to bring about early germination, but should additionally retain its moisture sufficiently long to permit of the healthy and early development of the young plants.

**Sorghum.**—Our experiments showed that sorghum seed could not with safety be placed at too great a depth, particularly if the soil be at all heavy. Hence we stated at the time that the most suitable depth for sowing was represented by the most superficial layer, sufficiently moist to offer good germinating conditions; and preferably 1 in. to 2 in. for heavy soils, and 2 in. to  $2\frac{1}{2}$  in. for light soils.

**Millet.**—We found that the germinating powers of millet seed usually sold locally are generally very weak, even under the most favorable conditions. Millet seed is very small, and should be sown as near to the surface as weather conditions permit of; not more than  $1\frac{1}{2}$  in. in light soils, nor more than 1 in. in heavy land.

#### THE DISTILLATION VALUE OF SURPLUS RAISINS.

This is not a question of immediate interest to farmers generally; nevertheless, it touches very closely another class of producers, and I make no apology for including it with the work we have been doing. In 1908 it was pointed out to me that surplus raisins were being sold to distillers for distillation purposes, and that the amount of spirit that could be extracted from them was naturally the basis on which they were valued. Growers, however, were more or less in the hands of the distillers, since the latter alone could put a true commercial value on the raisins. Distillers stated that they could not extract more than 75 to 80 gallons of proof spirit from

a ton of raisins, and wished to value them accordingly on that basis. Samples were submitted to me for an opinion. I found subsequently that 150galls. to 155galls. of proof spirit could be extracted from a ton of first-grade raisins, and 130galls. to 135galls. from second-grade raisins. My results were hotly contested at the time, but quite recently I have had the pleasure of knowing that they have been amply confirmed on a large scale by a Victorian distiller.

#### CONCLUSION.

I am rather inclined to think that I have perhaps trespassed unduly upon your time; let me assure you, however, that I cannot pretend to have done more than draw your attention to some of the principal lines of work that have occupied us over the past 10 years, and the results of which have already been published. There are many other matters that await analysis and publication; and in the course of time you will, no doubt, hear of them. I trust that you will agree that we have not been wasting time during the past 10 years. I entertain the hope, too, that some of our work will prove of direct benefit to South Australian farmers.

#### THE DISCUSSION.

Mr. A. L. McEwin (Blyth) said he had tested the matter of deep versus shallow ploughing, and had found that ploughing to a depth of 6ins. gave lowest results, whilst land that was simply cultivated returned up to 30bush. per acre. The difficulty was that the land was not always in a suitable condition to cultivate. He did not think it wise to plough stable manure into the ground; in fact, he was glad to get rid of it.

Mr. T. Collett (Strathalbyn) made a practice of putting the stable manure on the land in October, and ploughing it under the following July. For his district Cape barley was the best winter feed. A trouble he had experienced with rape, sown in February, was that while it did remarkably well until May, with the advent of the cold weather it turned red.

Mr. J. W. G. Mann (Cressy) strongly advised the application of every available load of stable manure to the land, especially in the case of sandy soils, such as were met with in his district.

Mr. T. Collett (Strathalbyn) wished that he lived near Mr. McEwin, so that he could get some of that farmyard manure. (Laughter.) Farmyard manure was one of the best manures procurable.

Mr. H. Ledger (Pinnaroo) said his experience with farmyard manure was that it could not be improved on. He had been much

impressed with the quantity of green stuff grown by Professor Perkins at the College. His experience with berseem in the mallee had not been favorable, but he considered lucerne the best stand-by possible. He strongly advised farmers not to try deep ploughing in the new mallee lands.

Mr. F. Masters (Roberts and Verran) said that in his district on Eyre's Peninsula the settlers had many problems to face. Of course, in a newly-settled district it was impossible to start straight off with mixed farming, but he believed if they followed the lines laid down by Professor Perkins they would find it of great benefit. He believed that the use of farmyard manure would prove of great value in his district, and that it would increase the stock-carrying capacity of their land.

Mr. F. M. MacMillan (Bookpurnong East) asked if hay was cut in full bloom how long it should be allowed to lie in the stooks before being stacked.

Mr. R. E. Lines (Gladstone) asked if 1lb. of good hay chaff per day would keep a dry ewe in good condition.

A delegate from Bookpurnong East stated that he had bought some sheep from New South Wales, and they had brought in their wool some saltbush seeds. This year, as a result, saltbush plants had sprung up all over his land, thus enabling him to carry over his stock. He asked if anything had been done in the way of experiments with saltbush.

The Director of Agriculture, replying, said he was glad to note that the bulk of those present still appreciated the value of farmyard manure. If grazing improved the land because of the droppings from the animals, surely they would agree that a light dressing of farmyard manure had similar results. As to whether sorghum interfered with the following wheat crop, they had for years carried out careful experiments on that point, but unfortunately the soil was a fairly heavy loam, and therefore not ideally suited to sorghum. Speaking from memory, the difference in the crop that came off land that had grown sorghum and the crop that came off bare fallow was, for a period of nine or 10 years, something like 4bush. That, he supposed, was the amount of the damage to the wheat crop done by growing the sorghum. They had to face the position that growing sorghum might reduce the yield of wheat that followed it; but sorghum was, in certain cases, so useful that they had to grow it. He knew a number of farmers had a prejudice against feeding horses on barley. In Asia, Africa, and Southern Europe oats were never fed to horses; the horses were fed on barley and straw. He had known horses do very well on

barley. Two years ago, at the Roseworthy College, they were very short of hay, and they cut the horses down to a ration of straw and barley, with the result that the farm manager told him that the horses never looked better or stood the work better than they did that year. Speaking from memory, he thought each horse at first got 5lbs., and then from 10lbs. to 15lbs., of barley per day, and as much straw as they could eat. It was dangerous to feed new barley in any other way than soaked. They reaped the barley, and did not, if possible, use it until after two months; it might, however, be used straight from the reaper if soaked. In ordinary circumstances it was not advisable to feed barley whole, as much of the grain passed in the faeces; it should then be crushed or soaked. To sheep it could be fed whole. One delegate had asked if 1lb. of chaff per day was enough for a sheep which was handfed. He could not remember exactly what they gave their sheep at Roseworthy, but certainly it was more than 1lb. each per day. Then the size of the sheep had to be taken into consideration. For instance, a Lincoln sheep would eat more than a Merino. It was not only a question of keeping the sheep from starving; it had to be kept in good condition, and to do this 1lb. of chaff was insufficient. The figures he had quoted in his paper—from 2lbs. to 4lbs. daily—was the amount necessary to keep the animal, according to its size, in a proper condition. He did not think Berseem would successfully grow without irrigation. He had never recommended it for the mallee districts. If they had heavy soil and water for irrigation it was a different proposition. That was what were required for Berseem to do well. Another point was that it was practically useless to try and raise it late in the season; it must be raised in March, and then, if the land had been properly worked, they would get, as he had stated, four or five cuts a year. Feeding cows on the Egyptian clover gave no taint whatever to the milk. With regard to depth of ploughing, he had been careful to state that the experiments had been conducted for a few years only, and that therefore definite conclusions would be premature. He would be very pleased to see careful experiments as to depth of ploughing carried out in various parts of the State. At present many statements were made which were based on insufficient data. He agreed that experiments with saltbush might well be undertaken, and hoped to do something in that regard in the future. (Applause.)

Congress at this stage adjourned till the following morning.

(To be continued.)

## THE WHEAT MARKET.

The fixing of prices by the New South Wales and Victorian Governments, the action of the Federal Government in practically prohibiting exports, and the drought in South Australia formed a combination of circumstances which seriously unsettled the local wheat market. Very little business was done, and with the continued absence of rain in this State it is not likely, apart from the war, that holders will manifest much inclination to quit.

Commenting on the wheat position in the United Kingdom at the end of August *Beerbohm's Corn Trade List* states:—"Harvesting has made good progress, both in the United Kingdom and in France, and as most of the wheat has been secured in good condition large supplies of native descriptions must be shortly expected on the different provincial markets. There is always more or less pressure to sell for a few weeks when the new crop is available, and this pressure (if anything) is likely to be more pronounced than usual, as money will be more than ever wanted this year. Under these circumstances it is most probable that, with fair shipments from North America, increasing supplies of native wheat, and further arrivals at United Kingdom destinations of wheat previously intended for Germany, supplies for some time to come will be in excess of requirements, causing stocks to increase. It is quite possible, however, that there will be more wheat exported from the United Kingdom than for many years past. Prices, notwithstanding the recent sharp decline, are still several shillings higher than a month ago, the improvement in values being caused partly by the war, and partly by the serious deterioration in spring wheat prospects both in Canada and the United States, especially in the former country. The position, so far as the world's supplies are concerned, has certainly moved in sellers' favor during the past four or five weeks, but under the exceptional conditions now ruling it is difficult to form any decided opinion regarding the movement in values. It is pretty certain, however, that Italy, Belgium, and France will all want fair quantities of American wheat as—so long as the Dardanelles are closed—there is little to come from other countries. If the war goes against Germany shipments from Russia will probably be resumed much sooner than otherwise would be the case, as Turkey would then remain neutral, and in that event Italy and the South of France would draw most of their supplies from South-East Europe.

"The American markets have again fluctuated violently. The belief held on the other side that the war will cause a high level of prices to obtain throughout the season causes a good many farmers to hold back their wheat. The visible supply (*Bradstreet's*), notwithstanding only moderate shipments last week, decreased 317,000bush., against an increase last year of 2,722,000bush. So far the receipts at western points have been only 17,000,000bush. in excess of last year's quantity, whilst the winter wheat crop is 152,000,000bush. larger than in 1913; it is therefore, very doubtful whether the holding back so early in the season can be of sufficient importance to have much effect."

The cessation in chartering caused by the European war and the drought in South Australia continues. The rates given below are consequently nominal.

STEAMER FREIGHTS.—(October 1st).—Full cargoes, South Australia to United Kingdom, 27s. 6d. per ton (8½d. per bushel); to South Africa, 27s. 6d. per ton (8½d. per bushel). Parcels, Port Adelaide to London, 20s. per ton (6½d. per bushel) plus 20 per cent. war surtax; to South Africa, 26s. per ton (8½d. per bushel), plus 20 per cent. war surtax; Port Adelaide to Melbourne, 12s. per ton (3½d. per bushel); to Sydney, 14s. 6d. per ton (4½d. per bushel).

SALES FREIGHTS.—From South Australia to United Kingdom, 2s. per ton (8d. per bushel); to South Africa, 22s. 6d. per ton (7½d. per bushel).

## DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Department reports on October 1st—

**BUTTER FACTORY.**—Though there was no decided increase during September in the quantity of cream received, there was a gradual rise from week to week. The butter was up to its usual high standard, and the sale was large. The present price of superfine is 1s. 2d. per pound, and pure creamery 1s. 1d. per pound.

A. W. Sandford & Co., Limited, report on October 1st—

**BUTTER.**—Notwithstanding the unfavorable season, supplies of both cream and butter show a marked increase during the month compared with September, 1913, but the improvement is only in the southern districts. However, present prospects look like a shortage throughout the season, so that there will be no surplus for shipment to Great Britain this year. Values throughout the month have been very steady, "Alfa" selling at 1s. 2d. per pound; "Primus" 1s. 1½d.; choice separators and dairies, 11½d. to 1s. 0½d.; store and collectors', 10d. to 10½d. per pound.

**EGGS.**—Prices showed slight fluctuations, and although larger quantities are coming forward, heavy oversea orders, coupled with local picklers operating, are keeping the rooms nicely cleared. Hen are selling at 8½d. per dozen; duck, 9½d.

**CHEESE.**—Rates are a shade easier, but the turnover has been very extensive, local consumption being good, whilst export orders have been large. Present quotations are from 6d. to 6½d. per pound for large to loaf.

**BACON.**—Demand throughout the month was somewhat quiet, which is usual for September; but with warmer weather we look for an improvement. Best factory-cured sides, 8½d. to 9d. per pound; rolls, 8½d.; hams, cooked, 1s.; uncooked, 10d. to 11d.; lard, in skins, 8d.; bulk, 7d. per pound.

**HONEY.**—Last season's yield has all been taken up, and buyers are now waiting for the new take. Prime clear extracted is selling at 3½d. per pound; beeswax, 1s. 2½d.

**ALMONDS** are very scarce, last season's crop being exhausted. Brandis, 7½d. per pound; mixed softshells, 7d.; hardshells, 4d.; kernels, 1s. 7d. per pound.

**LIVE POULTRY.**—The penning throughout September was very heavy, but unfortunately a large percentage were birds of only medium grade. Where quality was right very good prices were secured, but poor and light sorts sold according to condition. Good table roosters brought 3s. 3d. to 3s. 8d. each; nice conditioned cockerels, 2s. 3d. to 2s. 9d.; hens, 1s. 6d. to 2s. 2d. (a few coops of light sorts selling lower); ducks, 2s. 3d. to 3s.; geese, 3s. 6d. to 4s.; pigeons, 4½d. to 7d.; turkeys from 6d. to 8d. per pound live weight for fair to good table birds.

**POTATOES AND ONIONS.**—Potatoes have been offering freely, and prices have gradually eased, and although there are fair stocks still visible in the Mount Gambier districts, buyers generally have preferred the better samples that have been obtainable from Victoria. Onions—The high rates have had the effect of considerably contracting business, and supplies have come chiefly from Victoria. Present quotations are—Potatoes, £4 15s. to £5 15s. per ton of 2,240lbs. on trucks Mile End or Port Adelaide; 6s. to 7s. per cwt. in the market. Onions, £11 10s. per ton of 2,240lbs. on trucks Mile End or Port Adelaide; 13s. per cwt. in the market.

## RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of September, 1914, also the average precipitation to the end of September, and the average annual rainfall.

| Station.                   | For Sept., 1914. | To end Sept., 1914. | A'v'ge. to end Sept. | A'v'ge. Annual Rainfall | Station.               | For Sept., 1914. | To end Sept., 1914. | A'v'ge. to end Sept. | A'v'ge. Annual Rainfall |

\* No report received during the month of September.      † Formal report only received.  
 ‡ Held over until next month.

## ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

November 11th and December 9th.

## THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

### REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

#### UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

ARDEN VALE AND WYACCA (Average annual rainfall, 16.65in.).

August 31st.—Present: five members.

**CARE OF HARNESS.**—The hon. secretary (Mr. O. E. Hannemann) read a paper on this subject. He advised members to wash and oil all harness at the least once a year. If it was very hard and dirty the harness should be soaked in a tub of rain water and then scrubbed. After cleaning plenty of time should be given for it to dry thoroughly before applying oil. Buckles should be placed so that they did not always bear on the same place. For an example he mentioned the buckle bearing on the head piece of the winkers. By taking this up a hole on one side and letting it out a hole on the other side it would greatly lengthen the life of this piece of harness. In the ensuing discussion the chairman (Mr. J. H. Willis) advised placing a piece of leather between the buckle and the leather. Mr. E. Klingberg produced a sketch of a handy and cheap farm gate, the cost of which would be about 12s. He had one in use at present that was erected 30 years back, and it was still in good condition. He preferred wooden to iron gates, as they were more easily repaired.

COOMOOROO (Average annual rainfall, 11in. to 12in.).

September 5th.—Present: five members and three visitors.

**WOOL-CLASSING ON THE FARM.**—A paper on this subject was read by Mr. E. W. Brice. The farmer with a few sheep suffered a greater loss proportionately than the large sheepowner through carelessness in preparing wool for market, he said. There was no need to pay a skilled man to class farmers' clips, for a little care and commonsense was all that was necessary. The best price could not be expected when different kinds of wool were bundled together, or Merino and Crossbred were mixed in the same bales. Similarly the inclusion of dirt, chaff, etc., in bales or bags, loose packing, or other evidences of lack of care inevitably lowered the price. The shearing should be done on a clean floor, or the wool would become dirty. All fleeces should be skirted deeply. In many cases only the dirty edges need be taken off. In other cases, where the wool was of a very light condition, it would pay to skirt the burry pieces. The fleeces should be rolled neatly from breech to shoulder, and on no account should they be tied with string. Heavy, matted, or discoloured fleeces should be broken and mixed with the skirts. It was well to pack ballies, pieces, locks, and stains separately, as even if they were packed in bags, for mixed lots, they seldom brought full value. The bales should be branded legibly, with the name of the farm or owner, as insufficient branding often leads to trouble. Members generally agreed with views expressed in the paper. The writer of the paper further stated that he preferred the blades to the machines for shearing, contending that the machine shears spoil the wool to a certain extent, and that the sheep were knocked about a great deal more by them.

**HOOKINA (Average annual rainfall, 12in.).**

September 1st.—Present: seven members.

**BREEDING AND MANAGEMENT OF FARM HORSES.**—Mr. F. Stone contributed a paper on this subject. He preferred a heavy class of horse, low and thick, with deep girth, short back, well ribbed up, clean in the legs, good bone, and plenty of muscle, of good appearance, and a good walker. There was a better market, he said, for the heavy horse. He advised farmers on large holdings to breed a couple of foals each year, and so keep up the number of the team with young horses. Colts should be broken at between two and a half and three years, provided light work was available, and if placed in a big team, working abreast, early, they should be very carefully mouthed. He recommended walking at the side, and not in front, of colts when teaching them to lead. The young animals should become accustomed to the chains before being worked in the team, as there was a danger of their pulling about and making the older horses troublesome. They should be worked for short periods only for some time. Care should be taken to see that the collars fitted well, and did not gall the shoulders. He preferred to keep a set of harness for the separate use of each horse; and this should fit well and be carefully buckled. The animals should never be overworked, and always fed and watered regularly. Mares in foal could safely be given light work to within a few days of foaling. The use of the cross rein in big teams lessened the strain on the outside horses, and the team could be handled more easily. It was almost unnecessary, he said, to shoe the draught horses in this district, although buggy horses and hacks needed this protection. Good hay was equal to chaff for feeding, and he preferred oats to wheat as a grain ration. A good stallion should be selected and put to the best of the breeding mares only. A discussion followed. Opinion was divided as to which was the best class of horse for farm work. Most members favored the medium draught, as it stood periods of drought better than the heavier animal. The Chairman considered that it was important when breaking colts to accustom the animal to the master's voice. Mr. Kelly would breed the heavy draught, which could be placed on the market in times of drought, and would bring a good price. Mr. McCann thought two and a half years too young to break colts. He would place them in a wagon team.

**MORCHARD (Average annual rainfall, 11in. to 12in.).**

August 29th.—Present: eight members.

**PAINTING BUGGIES.**—In a short paper on this subject, Mr. Laske said it was necessary before painting a buggy to thoroughly clean and sandpaper it. Vehicles that had been painted before should prior to re-painting receive a coat of stain paint. Careful protection against dust should be afforded, and only best paints should be used. Two days were required for the first coat to dry. Care should be taken to strain the paint, and so remove any scum that might have formed on the surface. Ample time should be left for the paint to dry thoroughly before the vehicle was used. Members discussed the matter, and generally agreed with the opinion expressed by the writer of the paper. Messrs. W. Toop, J. H. Riechstein, E. J. Kitto, W. E. Toop, and the Hon. Secretary (Mr. H. G. Kupke) took part.

**WEPOWIE, September 1st.—INCREASING THE USEFULNESS OF THE BUREAU.**—A short paper on this subject was read by Mr. C. Halliday. He emphasized the necessity for, and value of, experimental plots. Poultry, he said, should be given more attention, as in very bad seasons they represented the only source of income on some farms. Members of the Bureau should report anything that might be of interest to any other members.

**MIDDLE-NORTH DISTRICT.****(PETERSBURG TO FARRELL'S FLAT.)****BEETALOO VALLEY (Average annual rainfall, 18in. to 19in.).**

August 31st.—Present: six members and one visitor.

**HORSE BREEDING.**—The secretary (Mr. P. Curtin) read a paper on this subject. He advocated breeding from the best mares only. These should be short-legged, round in the girth, and have well-sprung ribs, short back, broad and

deep shoulders. They should not be stinted too early if required in connection with fallowing. He considered the end of September the best time; this would give an August or early September foal. He would only breed from the same mare every other year, as this produced a better foal; mares bred from every year became sluggish. The sire should be of a good pedigree. He would then be more likely to pass on his good points to his progeny. A mare that had a bad point should be put to a stallion that was excellent in that particular respect. Mares could be worked to within four weeks of foaling. Foals should be weaned at about six months (say in March), and placed in a well-enclosed paddock, where they could get plenty of exercise. They should be well fed on a little hay, chaff, or bran, and kept growing. When weaning foals it was advisable to teach them to lead. In discussing the paper Mr. Bartrum considered mares should foal in August. Mr. Murphy would breed every second year from mares that did the usual work on the farm, and Mr. Jacobi recommended weaning by placing the mare on one side of the manger and the foal on the other.

BELALIE NORTH (Average annual rainfall, 16in. to 17in.).

July 4th.—Present: 14 members and four visitors.

**COLIC.**—The following paper was read by Mr. F. D. Bladon:—"Colic is the manifestation of pain in the interior of the abdomen. It is a symptom of various diseases, such as irritation of the intestines, due to indigestion, worms, enteritis, hernia, twisted bowel, and any obstruction in the system. It is stated that about 40 per cent of the attacks of internal diseases of horses may be put down to colic. The mortality from it is about 13 per cent., or about 40 per cent. of the general death rate. It is a grave mistake to give a horse medicine unless one is certain of the effect the medicine will have on the horse's system. To ascertain whether a horse is suffering from stoppage of the water or not, place the hand inside the anus, and there feel the bladder extended, if full. If in its normal condition, the pain must arise from some other source. There are five divisions of colic—(a) Colic in its simple form, which generally arises through the food eaten, which disagrees with the stomach; 99 per cent. of cases will recover from simple colic without any administration of drugs. (b) Spasmodic colic is a term applied to spasm of the muscular coat of the intestines, generally caused by irritation due to the presence of undigested food; it may also be occasioned by chill. It is usually brought on by injudicious watering and feeding, especially when the horse is exhausted by hard work and long fasting, for the digestive apparatus is then in a weakened state. (c) Flatulent colic is rather a dangerous form. It is due to the distention of the bowels by gas resulting generally from the decomposition of undigested food. It sometimes follows spasmodic colic, in which case we have in the first instance spasms, due to irritation set up by the presence of undigested matter; and, subsequently, distention owing to its decomposition. Horses which are fed on large quantities of boiled food frequently become chronically disposed to attacks of flatulent colic, from the fact of their stomach having become weakened from continued over-distention. The symptoms resemble those of spasmodic colic, except they are less violent, though more continuous, and there is considerable distention of the abdomen, which is well marked in the hollow of the flank. (d) Flatulent distention of the stomach, which is the return of food, or belching of gases from the stomach of the horse. This is practically prevented by the fact that the calibre of the gullet, at its opening into the stomach, is particularly small, and that it is completely obstructed by folds of mucous membrane. (e) Worm colic is caused by the over-abundant presence of worms in the system. This disease is frequently called enteritis, commonly known as inflammation of the intestines. From the enumeration of the causes of colic we can see that what may be a curative in one instance might be fatal in another. For instance, a dose of aloes would speedily remove pain due to recently eaten undigested food in the system. It would be a bad thing to give a horse for long constipation, as it would probably cause a rupture of the stomach. The symptoms of spasmodic colic are, usually, disinclination to go on if at work, depression, uneasiness, pawing with front feet, arching the back, looking around at the flank, and making attempts to lie down, which the patient does very carefully

at this stage. As the disease proceeds the animal may cow kick at his belly, or seek relief from pain by rolling on the ground. During these times the pulse will be frequent, breathing labored, and body more or less covered with perspiration. The usual dose for colic is 2oz. of turpentine in a pint and a half of linseed oil; if the pain is severe, add an ounce of chlorodyne, and if unable to procure this dose, give carbonate soda, one tablespoonful. In cases of flatulent colic, back rake and give an enema of 3galls. or 4galls. of soapy water. Farmers should realise the importance of feeding their horses, and they would prevent a good deal of these diseases. The manger should be well supplied with rock salt, and Epsom salts should be given regularly in feed during winter months, when the feed is dry. Salts will act as a substitute for green feed. Horses are certainly dumb animals, but they are so valuable to the farmer in his work that they warrant a good deal more consideration than they generally get.

**MARES AND FOALS.**—Mr. Cummings read a paper dealing with the breeding of foals. He preferred a draught mare of good quality, roomy, staunch, good tempered, quick moving, and with the maternal instinct strongly developed. The Clydesdale sire was recommended. When hand-rearing motherless foals, generally considerable trouble was experienced with scouring, caused by irregularity of feeding, or milk given at the wrong temperature. Cows' milk for calves should be diluted with one part of water to three of milk. The foals should be gradually accustomed to solid food; all corn should be crushed. They should be weaned at six months, and broken at 2½ years. Up till this time they should be handled. Mr. O'Niell had successfully reared a foal by putting it with a mare rearing her foal. He kept winkers on the mare for three weeks, after which she cared for the orphan.

#### BOOLEROO CENTRE (Average annual rainfall, 15.83in.).

August 28th.—Present: 15 members and two visitors.

**CARE OF HARNESS.**—Mr. G. R. Hein read a paper on this subject. He expressed preference, in dealing with the matter of the selection of harness, for pipe collars, which he thought were not so liable to choke down the horses. He recommended the selection of long-pointed hames, as with these the draught was more easily adjusted. Horses, especially those that were inclined to "slacken off," should be driven in winkers. Harness should be dressed twice a year with a mixture of neatsfoot oil and mutton tallow in equal parts. He concluded the paper with a number of hints regarding the care and attention necessary for farm harness. In discussing the subject, Mr. W. H. Nottle advised the application of castor oil as a harness preservative.

**GARDENING.**—At a previous meeting Mr. G. Ashby dealt with this subject in a paper, in introducing which he mentioned the advantages accruing from a well-kept garden. He recommended making a start as soon as a good rain was experienced. The ground should be dug or trenched, and then dressed with manure (stable for preference). Digging should again follow, and if possible this operation should be performed a third time. In planting, sufficient room should be left between seedlings to enable them to develop properly, and constant stirring of the soil would be found necessary to keep under the weeds. He also made a plea for the improvement of homesteads by planting the land surrounding with shrubs and trees. The paper was well discussed by members.

#### LEIGHTON (Average annual rainfall, 16in. to 17in.).

August 1st.—Present: 17 members and six visitors.

A short paper on stack building was read by Mr. E. Jettner. He advised placing a layer of straw beneath the stack to prevent the lower sheaves becoming musty. Square corners were preferable, as the round corners had a tendency to slip. Stacks should be built from the outside, and in tiering the second row should be placed butts outwards to the strings of the row directly below it. The centre of the stack should be kept slightly full, and the walls built with a slight lean outwards. The sheaves should be placed butt outwards for the roof. The general opinion of members favored round-cornered stacks, the centre being built slightly higher than the outside and the roof, with the heads outwards. The vice-chairman (Mr. T. Goodridge) thought it advisable to construct a stone stand for haystacks, and to fence round these with iron to prevent mice destroying the hay.

**MUNDOORA** (Average annual rainfall, 14.11in.).

August.—Present: five members and one visitor.

**HIGH OR LOW GRADE SUPER.**—A paper on this subject was read by Mr. W. Stephenson. He gave a lengthy resume of an address by Professor William Lowrie, M.A., B.Sc., delivered at the Conference of Northern Branches of the Agricultural Bureau. (See page 958, April, 1914, issue.) Continuing, Mr. Stephenson said he favored colonial-manufactured super., as the imported article had a tendency to absorb a larger quantity of moisture, consequently becoming sticky, and causing the bags to rot. He recommended dressings of 80lbs. per acre where grain was to be reaped, and 100lbs. per acre for hay crops. Members discussed the paper at length.

**PORT PIRIE** (Average annual rainfall, 13.21in.).

August 1st.—Present: seven members and one visitor.

**STARTING A FARM.**—A lengthy paper under this heading was read by Mr. J. Greig. The first step to take, he considered, was to sink wells or a bore to obtain water. The homestead should be erected as near the centre of the farm as possible, and on high ground to ensure good drainage. He advised commencing the building in such a way that it could be conveniently added to at any future time. The same thing applied in erecting the sheds, stables, barns, &c. The barn and implement shed should be placed about 50 to 100yds. distant from the haystacks and stables, as a provision against fire; also, it was unwise to stack large quantities of hay in the yard adjoining stables and chaffhouse. The homestead and outbuildings should be enclosed in a fair-sized paddock, of from 80 to 100 acres. In addition to wheatgrowing, dairying, poultry keeping, pig raising, gardening, &c., according to the nature of the country, would be found profitable. He could not advise any definite time when to commence seeding, as the seasons were so irregular. He advised young farmers not to attempt too much at one time, but to do only as much as could be done thoroughly. All farms, he said, should carry a small flock of sheep, as they always proved a very payable side line if properly attended to, but over-stocking only courted failure. All implements should be put into the field in good working order to obtain best results, and the harness should be always kept out of the weather when not in use. Empty bags, too, should be taken care of from one harvest to another. Seemingly small items, such as these, the writer said, meant the saving of much money. In conclusion, he urged beginners not to be discouraged at small setbacks, but to stick at it, and finally they would succeed. In the discussion which followed, Mr. Munday agreed that it was a difficult matter to set down any definite period at which to commence seeding. He considered the centre of the farm the best position for the homestead, and plenty of room should be left for possible future extension. He recommended keeping cows, pigs, poultry, &c., according to prevailing conditions, as profitable side lines. Mr. F. Johns considered that well-bred stock only should be kept, and advised all farmers to carry a small flock of sheep. Harness should receive careful attention. Messrs. Kirchner and D. L. McEwin (president) endorsed these remarks.

**SPALDING** (Average annual rainfall, 20.25in.).

August 15th.—Present: eight members and two visitors.

**CARE OF FARM IMPLEMENTS.**—Mr. A. J. Howley contributed a paper on this subject. He advised members to soap the axles of vehicles and implements before greasing. The wheels should have 1-16th of an inch play. New axles should be frequently greased, as they were very liable to run hot. Care should be taken at all times to see that nuts were tightened up. Implement sheds should be built of stone, with iron roofs. He advised building the wagon shed with an opening at each end; the wagon could then be driven straight in, thus doing away with backing, which was at times troublesome. Where an old type hayframe was used, he would fix four pulleys to the rafters of the shed; the frame could then be hoisted from the wagon and hung there until again required. Before starting a sheaf-binder, the frame upon which the canvases ran should be set squarely. This could be done by adjusting the rods which ran from corner to corner on the frames. The canvas would not then need to be drawn so tightly. When shifting a binder the table lever should be so adjusted as to throw the weight of the implement evenly on both wheels. He deprecated the

use of neatsfoot oil as a lubricant. One gallon of good machine oil was more than sufficient to supply a machine whilst harvesting a 250 acre crop. The chain belts of both the binder and harvester should be placed so that they pulled from the thick end of the links. The main pinion or slow moving cogs of these machines did not need oiling but occasionally a little black lead would be beneficial. If properly set the pinion of the stripper would last 20 years, and that of the harvester 10 years. The beaters should be set as close as possible to the comb without striking, and kept perfectly tight. He would not have the set screws too tight. He recommended copper rivets for joining leather belts, and if the machine was kept in a shed it would not be necessary to remove the belt, but simply to loosen and oil it while the machine was idle. He made a practice of dotting down in a notebook any little defect he noticed in the machinery, and afterwards rectifying it in his slack time. All machines and implements should be thoroughly cleaned and overhauled before laying up for the coming season. He then mentioned the many uses to which certain parts of worn out machines could be put. In the discussion which followed Mr. J. H. Pluckrose recommended placing wooden wheels in a bath of hot raw linseed oil. Spade and fork handles, &c., would also benefit by this treatment.

#### YONGALA VALE (Average annual rainfall, 13in. to 14in.).

August 29th.—Present: nine members.

FALLOWING.—Mr. T. Keatley read a paper on this subject. He advised commencing fallowing as early as possible after good winter rains, to cause early germination of all seeds, the weeds from these being subsequently destroyed by the cultivator. The depth should be regulated according to the nature of the land. Light land, for instance, did not require to be worked to a greater depth than 3in. to 3½in., whilst in the red land 4in. to 4½in. was necessary. Limestone country was likely to develop bare patches if it were ploughed to too great a depth. He advised cultivating fallow, and would use harrows after every shower of rain. Members agreed that the practice of ploughing limestone ground to a greater depth than 3½in. to 4in. had a tendency to result in additional trouble with salt and magnesias patches.

BELALIE NORTH, August 8th.—Mr. Bladon initiated a discussion on "Co-operation Among Farmers." He was not in favor of same, as he thought it too big an undertaking for the farmers, and would not benefit them financially. Mr. Warner favored co-operation in the buying of groceries, &c., and manure, and in the selling of wheat. Mr. Dunstone believed that farmers would benefit by co-operating in the purchase of their implements.

MOUNT BRYAN EAST.—Present: Eight members.—Members generally agreed that the Merino was the most suitable sheep for this district, as the return from wool was reliable. With the crossbred—in the event of lambing failing—the wool return was very much less.

The Hon. Secretary tabled a sample of barley just coming into head at a height of 2ft. 6in., together with a sample of lucerne 18in. high. These were grown under irrigation.

### LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

#### BEAUFORT.

August 5th.—Present: 10 members and three visitors.

TREE-PLANTING.—The Chairman (Mr. W. W. Mugford) contributed a paper on this subject. The wholesale clearing of scrub, he said, had resulted in more trouble with drift in the paddocks, and to obviate this he advocated tree-planting. Each farmer should put in a number of trees annually. He had found sugar gums most suitable for this district. Pepper trees made good shade and shelter, but were of little use for timber, and it was unwise to put them too close to a house or garden. He gave statistics relative to the area under forests in Australia, and expressed pleasure that this subject was receiving more attention of late than had hitherto been the case. In discussing the paper Mr C.

Wilson agreed with the writer that the sugar gum was the best tree for this district, and advised placing guards round young trees. Mr. A. Yard had successfully grown these trees from seed. Messrs. G. Underwood and A. E. Sampson also took part in the discussion.

#### BEAUFORT.

September 3rd.—Present: 10 members and four visitors.

**WORKING FALLOW LAND.**—Mr. J. E. Marr contributed a paper under this heading. He advocated cultivating land for fallow between harvest and seed time, but not deeply. The first rains would bring up the weeds, which could be attended to after seeding. The cultivator, he said, mixed the soil better than the plough, and did not turn the poor soil to the top. He instanced a case of a farmer who used the cultivator only for fallowing, and had averaged 30bush. up till last year, when 16bush. were reaped in spite of the dry season. This man's neighbor had used the plough, with the result that the ground was lumpy, and he had not been able to reduce it to a fine surface after harrowing, rolling, and cultivating it. Cultivator fallow was standing the dry spell well this year. In discussing the subject Mr. P. H. Underwood agreed with the writer of the paper. After seeding he would go over the land again with the cultivator to a depth of 3in., or a skim plough could be used. Mr. A. Yard preferred the skim plough. The chairman (Mr. W. W. Mugford) would not use the plough, except on hard ground. It was unwise to work the land when very dry, and he deprecated the practice of turning under the straw. Mr. G. W. G. Underwood favored the spring-tooth cultivator for working fallow, and would use the skim plough after seeding. Mr. J. Sampson would fallow between harvest and seed time to a fair depth, and considered the skim plough a good implement. A visitor favored the cultivator, and another favored this implement for dry years, but would use the plough in seasons of good rainfall. He would not turn the rubbish down in dry years, but leave it on the surface to assist in the retention of moisture.

**BLYTH** (Average annual rainfall, 16.46in.)

August 8th.—Present: seven members.

**TREEPLANTING IN SOUTH AUSTRALIA.**—Mr. R. Buzacott read a paper on this subject. He referred at length to the destruction of timber in this State, and urged a policy of replanting. Waste land, i.e., that unsuitable for wheat-growing, could be planted during wet seasons. Unused district roads could be ploughed, cultivated, and planted with suitable timber trees. Corners of paddocks could also be put under forest trees. Hills in the vicinity of Blyth, which were carrying very little grass, principally a black tussock, would be very greatly increased in value if planted with pines. He also mentioned the efforts of the local Vigilance Committee to encourage treeplanting by offering prizes for the most successful attempts at treegrowing by the school children.

**FREELING** (Average annual rainfall, 17.85in.)

September 16th.—Present: 14 members.

**COST OF PRODUCING HAY AND WHEAT.**—Mr. J. E. Neldner read a paper dealing with the increasing cost of producing wheat and hay. He dealt at length with the various factors which were contributing to this increase. He estimated the cost of cropping an acre at £2 17s. 6d. A 2-ton to the acre crop, which he considered fairly high, at 35s. per ton for hay in stack, would return £3 10s., showing a profit of 12s. 6d. per acre. A 20bush. crop of wheat, sold at 8s. 6d. per bushel, would show the same profit.

**STOCKPORT** (Average annual rainfall, 15.89in.)

August 28th.—Present: 14 members.

In reply to a question Mr. Watts considered that, in view of the very bad condition of the crops, it would be wise to feed them off, and sow for summer fodder. He intended to try sorghum, maize, and rape. Mr. Whitelaw had turned his stock on to a paddock that had been cross-sown with wheat and oats. After they had eaten it down he placed them in another paddock which had been dry sown—this pulled up badly. Mr. Stribling would not feed off the crops, as with rain in the spring, some fair crops might yet be reaped. Mr. J. Howard stated that the ground was very loose this season, and therefore much of the

crop pulled up. Mr. Megaw noticed that land not worked until seeding time had stood much better than that which was well worked last summer. Kerosene and oil was recommended as a good cure for pig tick.

**BEAUFORT.—CORRECTION.**—We have been asked to make the following corrections. July issue, p. 1314.—Mr. J. Sampson was reported to have said "Tick and lice would not thrive on sheep in this district. This should have been "tick would not thrive on sheep in this district." August, p. 74, Mr. W. W. Langford is credited with the statement that "He thought it more difficult to get a wet mare in foal." This should have read, "He thought it easier to get a wet mare in foal than a dry one." Also, Mr. Sampson is reported to have stated, "It was no harder to get a wet mare in foal than a dry one, if she were in good condition." This should have been "It was no harder to get a dry mare in foal than a wet one, if she were in good condition."—Ed.]

**WATERVALE, August 31st.**—Mr. G. Holder initiated a discussion on co-operation among farmers. **FRUIT-TREE MANURES.**—This subject was then discussed by members. Mr. A. Burgess recommended bone super as a good all-round manure. Potash was good, but rather expensive. Mr. Holder considered that, if obtainable in sufficient quantities, stable manure was good. He had applied a mixture of 1 part of potash to 4 parts of super with good results. Members generally considered that it was not necessary to drill the manure in to any depth.

## WESTERN DISTRICT.

**GREEN PATCH** (Average annual rainfall, 26.56in.).

August 31st.—Present: 13 members and six visitors.

**BULK HANDLING OF WHEAT.**—This subject was dealt with in a paper by Mr. C. Venning. This State, he said, having so many ports from which wheat was shipped, would not benefit by this system of handling wheat, and also, insufficient grain was annually exported to warrant the introduction of this method. It would be time enough, he said, when we had millions of acres under crop, with an average yield of from 20 to 30 bushels. Bagged grain was preferred by the millers. If bulk handling was introduced, farmers would receive less for their produce, and the markets would be restricted. Elevators would necessitate centralisation, and this would mean, in many instances, long rail carriage, and consequently big freights. In discussing the paper members generally agreed that this State was not suited to the bulk handling system, and that the method, if introduced, would not pay, although the grain could be graded better.

Members then discussed the fox question, the consensus of opinion being that the fox was doing more harm than good.

Mr. Sage, speaking on poultry keeping, informed members that for the year 1913, the food bill had run out at 3d. for every dozen eggs produced, and up to the present for this year, at 3½d. per dozen eggs produced.

**PENONG** (Average annual rainfall, 11.93in.).

August 8th.—Present: seven members.

**TREATMENT OF HORSES.**—The chairman (Mr. C. Farrelly) read a short paper under this heading. He preferred a horse with a good body, round in the barrel, good flat bone, and plenty of fine hair, of very sound constitution, and upstanding. He condemned the practice of overworking a horse, and emphasized the necessity for feeding regularly. Oats were better than wheat, and at least one feed a week of bran should be given. It was a mistake to roughly handle a horse, as this only tended to make it timid. Better results would always be obtained by kindness. He attributed sore shoulders to carelessness, as this trouble could be prevented by well grooming the animals and giving the collars proper attention, boating out all lumps in the stuffing. The collars should fit well, but if they happened to be a trifle large, he would place bran bags (without any creases) under them. In discussing the paper Mr. O. J. Murphy recommended the Percheron as the best type of farm horse, and advised bathing sore shoulders with

lysol in hot water. For sore shoulders Mr. W. Saunders recommended removing the collar and replacing with an old one, which should have new lining sewn on in such a way as to raise the collar over the sore. He also considered daily grooming necessary. Mr. J. Oats preferred the nuggety horse for all-round farm work, which he would breed himself, to ensure it having a good constitution. Mr. J. Saunders considered Clydesdales the best type, and agreed with Mr. Oats that farmers should breed their own horses.

#### ROBERTS AND VERRAN.

September 1st.—Present: 10 members and five visitors.

**SUMMER FODDER.**—A paper on this subject was read by Mr. W. A. Whittaker. During the past four years he had sown Rhodes grass, cocksfoot, rye grass, sorghum, *Paspalum dilatatum*, lucerne, and several others, and had found lucerne the best, as in this district it grew for 10 months of the year, and came on quickly after being fed off. He had drilled in lucerne seed with his wheat, but the results had not been satisfactory. Subsequently he broadcast 6lbs. of seed on one acre of fallow, which had been dressed with 1cwt. of super., and afterwards harrowed. He then hand sowed (on 10 acres which had been ploughed early in March and drilled with oats) 10lbs. of lucerne to the acre, and harrowed it. The oats were cut for hay in November, and at that time there was a good growth of lucerne, about 4in. high. In March of last year he lightly ploughed an acre of land, on which the clay was very close to the surface, and drilled in oats and lucerne. Twenty-five per cent. of the lucerne grew, and in November the average height of the plant was about 2ft. 6in. The rainfall for the year was 10.1in. Sorghum had been successfully tried. Perennial rye grass and Rhodes grass had also been satisfactory. Messrs. H. Whittaker and Kruger advised sowing the sorghum on sandy soil, and Mr. F. Masters advised sowing the perennial saltbush.

#### YADNARIE (Average annual rainfall, 14.09in.).

September 4th.—Present: 14 members and four visitors.

**PROFIT FROM SMALL PRODUCTS.**—A paper on this subject was read by Mr. W. I. Brown. He emphasized the value of properly preparing for market all commodities. Sheep skins should be painted with a skin wash, immediately after removal from the carcass. The skins should then be hung lengthways over a rail in a shed, until dry. The wool should be kept free from blood stains. This could be achieved by killing the sheep on a sloping grating. It was a more difficult matter to keep the blood off bullock hides, but salt freely applied within a short space of time would take the stains out. The hide could be drained by laying it over a mound of earth for a few hours. In respect of the tallow, hessian or sacking should be tied over the tin into which the hot fat was poured to arrest all foreign substance. In discussing the paper Mr. A. A. Jericho said that sheepskins could with safety be hung over one another, but Mr. J. J. Deer deprecated this practice, whether the skins were wet or dry. The chairman (Mr. S. H. Pearce) said that placing the skins over one another encouraged weevil, and spoiled the wool. He would pin them down at the head and tail, and tie a light weight to each trotter. Mr. F. W. Dreckow stated that he had used skin wash with satisfactory results.

**CARROW, August 27th.—MALLEE SHOOT SCORCHER.**—Mr. C. Storrie read a short paper, in which he dealt with the great benefit that would result in mallee districts from the introduction of an effective shoot scorch. The majority of machines on the market were constructed to burn wood, and he thought better results would accrue from the use of oil fuel. Members discussed the subject at length.

**MANGALO, August 8th.**—Mr. J. Cleave delivered an interesting address under the heading of "How to make meetings more interesting." He gave a number of hints, by the adoption of which he thought the work of the Branch could be made more effective, and generally urged members to take a keen interest in the proceedings of the Bureau.

**SALT CREEK.**—A paper read by Mr. J. F. Jacobs at the July meeting (See page 86 of August issue) was re-read and discussed by members. Mr. Lee, sen.,

thought that if the co-operative system of marketing dairy produce were introduced it would tend to improve the quality of cows kept in the district. The Hon. Secretary (Mr. F. H. Hill) agreed.

YALLUNDA, August 29th.—Present: nine members and two visitors. The Hon. Secretary (Mr. J. W. Winch) read an article dealing with the influence of deforestation on water supplies. The paper was received with interest and discussed by members at length.

## EASTERN DISTRICT. (EAST OF MOUNT LOFTY RANGES.)

### BERRI.

August 29th.—Present: 32 members and three visitors.

VEGETABLE-GROWING.—The Hon. Secretary (Mr. W. R. Lewis) read a paper on this subject. He stated that practically all along the river good land was available for this industry. In a few places the soil did not require manures. Good loamy soil, sheltered if possible, should be selected. He had grown over 20 tons of onions to the acre, which realised £6 10s. a ton, on the river bank, and for 10 years he had averaged 12 tons. Early onion seed should be sown during the second week in March. The seed bed should be free from weeds. It was best to sow to a depth of about  $\frac{1}{2}$  in., and keep the plot damp by covering with hessian after watering. When transplanting the root growth should be cut back close to the bulb, and the tops should also be cut well back. The young plants should be placed in rows about 4 in. to 5 in. apart, with about 8 in. to 10 in. between the rows. Deep hoeing would possibly damage the roots. Cultivating was very important. He sowed Early Ballotta for the first crop, and followed with Brown Globe or Hunter River, and then Brown Spanish. For potatoes, he favored a good rich, sandy, loamy soil; plenty of water was essential. Up-to-dates, Snowflakes, Tasmanian Redskins, Beauty of Hebron, and White Elephants did well, but he had failed with Vermonts. Victory he had found particularly good. He had grown two crops in 12 months on the same piece of land, sowing the first from July 20th to the end of August, and had dug them in late November. These realised £14 to £16 per ton. The second crop could be planted in early February. He advocated dressings of stable manure or leaf mould. On poor land he would use 2 cwt. of super. and 150 lbs. potash. Where quick transit to the market could be obtained he advised growing tomatoes. He had realised as much as 24s. per case, and often 16s. per case for them. To produce the finest quality fruit the plants should be staked or trellised, and brought up to one stem, spur-pruned from the ground. The ground should not be kept too hot with stable manure. Where plenty of water was available French beans would yield enormous crops, Caseknife, Emperor William, and President Garfield being good varieties. Asparagus and snake beans had been grown, and although they yielded heavy crops, the staking was a great drawback. His conclusion was that dwarf varieties would always prove most profitable. They should be planted as soon as the ground commenced to warm; new land could be planted, if well worked, but on land that had been heavily manured he would first take off some gross feeding crop, such as cabbage or kale, then work it well before planting. Cabbages and cauliflowers needed very rich soil; an abundance of stable manure would be found to help these on. The difficulty with the cauliflower was to get good seed, which should be planted early in December or January. Cabbages could be planted out up till September, but cauliflowers not later than April. For these crops he had found no fertiliser better than pig manure; sheep manure was also advantageous, providing plenty of water was available. Henderson's Succession and medium drumhead were very good general market cabbages, and less likely to be affected with the blight than others. Such vegetables as pumpkins, cucumbers, etc., could also be grown to advantage in these districts. These needed pruning, and the cucumbers especially should be given plenty of water. Members appreciated the information contained in the paper.

## BORRIKA.

August 29th.—Present: 21 members and two visitors.

A member reported that crops on the plots sown on June 30th were now showing. A plot sown without super. looked as well as that with super.; but he was now afraid it would be a total failure. That sown with 84lbs. looked as well as that with 112lbs. super. Top dressing seemed to be the better, and land that had been harrowed retained the moisture better than the unharrowed. Mr. Wilhelm had sown wheat with Beats all and 20lbs. super., which looks well at present. Of two plots of Federation, one sown with Beats all and 40lbs. super., and the other with 40lbs. super. only, the former had proved superior. Mr. Brown (chairman) had sown on both stubble and fallow land of a red, sandy nature, and of a limestoney nature, and in each instance that on the fallow was superior. The stubble had been ploughed this season. Mr. Gray said his late-sown wheat had done better than the early-sown wheat. Mr. Searcy favored Marshall's No. 3 as a late, and Gluyas as an early wheat. Messrs. Collins and Bonython spoke in favor of Yandilla, which was holding out well despite the dry season; but Mr. Traeger considered this variety liable to rust. Marshall's No. 3, he said, was rust-proof. He had fair results with Western Wonder last season. Mr. Wilhelm stated that Federation grew better on new than on stubble ground. Mr. E. H. Huxtable thought Baroota a good hay wheat. Mr. G. Miell favored Le Huguenot, and Mr. Gray favored Marshall's No. 3, as besides being good for hay, it yielded plenty of grain. In reply to a question, Mr. Traeger said that Champion oat was the best for green feed, as it was a good yielder, and could be cut at almost any stage, and was liked by stock. Scotch Grey, he said, was a good yielder, but a short grower.

## COONALPYN (Average annual rainfall, 17.49in.).

September 4th.—Present: 10 members and three visitors.

QUESTION EVENING.—In reply to a question Mr. Hill considered that there was little danger in sowing seed from a crop which had been infested with "takeall." The spores of this disease remained in the ground, and its spread or otherwise depended greatly on the system of cultivation and rotation adopted. Mr. Bone would not take the risk of sowing such seed, however. Mr. Williams then demonstrated the preparation of vine cuttings. Mr. Pitman said that, when possible, he left a piece of the old wood on the bottom of the cuttings, and preferred them with the buds close together. He advocated securing rooted vines from a nursery when laying out a new garden. Mr. Venning said that on land with a sour clay subsoil near the surface he would not risk ploughing to a greater depth than two inches at seeding time. Deep ploughing new clay land, and then working down to a fine tilth was not advisable, even in a dry season, as the surface would cake after the first rain, and the moisture would be lost. He advocated, however, following such land to at least 4in. Asked as to whether it was possible to work cultivated fallow too much, Mr. Bone replied that it was not so. The more and the better the land was cultivated, he said, the better the result would be. Providing it could be worked properly afterwards, early fallowing was the best. He ploughed early to allow the weeds the benefit of the early rains. The stock should then be put on the land, but failing this, he would harrow down as smooth as possible. This would enable the next implement used to better pull up the weeds. Then the scarifier or cultivator should be used, as deep as possible, and be followed by another harrowing. It should then be ploughed and left for a few weeks. The harrow could again be used. He would harrow after rain as much as possible. Finally he would plough or cultivate before seeding.

## FORSTER (Average annual rainfall, 10in. to 11in.).

August 29th.—Present: six members.

LIME BURNING.—A discussion on this subject was initiated by Mr. J. Searle. The kiln, he said, should be made round and dug to a depth of from 5ft. to 6ft. He used a hollow log, with one side cut longer than the other at one end, to catch the wind and act as a draught hole. He found that small logs created the best heat. Mr. W. Searle had had good results with the round kiln. He recommended placing a pine log, big at one end, in an upright position in the kiln, and after the kiln had been filled up, he would pull up the pine and drop the fire down. Mr. E. Towill had used split logs with good results. Mr. F.

Searle considered that the result of the burn depended to a large extent on the nature of the stone. Hard stones made better lime than those that were soft. Mr. C. Hayman recommended covering the kiln, after it had been burning some time, with decaying chaff.

GERANIUM (Average annual rainfall, 16in. to 17in.).

September 4th.—Present: 13 members and two visitors.

STRIPPER V. HARVESTER.—Mr. L. Prouse contributed a paper on this subject. He favored the stripper, as it could be managed by any average lad, and, especially in sandy districts, the harvester was a trouble to keep in perfect working order. A stripper costing £60 would last as long as two harvesters, representing an outlay of £180. More waste was occasioned by the harvester. He considered the stripper seed wheat best, as wheat from the harvester was often unmatured. The cocky chaff saved through using the stripper over a 400-acre crop would, mixed with hay chaff, or damped with molasses and corn added, mean a saving of £15 or £16 for feed. He did not consider that the harvester gave such a clean sample as the other machine, and it also lost the screenings. A stripper could often be put into a field before the harvester could be used on the crop. Considerable discussion followed the paper. Mr. Norton favored the harvester, as the wheat could be carted as soon as reaped. Mr. Perrin favored the stripper as it conserved the cocky chaff, and was more suitable to the nature of this district. Mr. Greig preferred the harvester. Members' opinions were divided as to which was the best machine for this district.

#### KINGSTON-ON-MURRAY.

September 4th.—Present: 15 members.

FARMING IN MALLEE DISTRICTS.—In dealing with this subject, Mr. S. Pope said that he had found that from three to four inches was the best depth to plough for this district, and that it paid to fallow and work the ground well so that when the seed came up the crop would not be half grass and half wheat. He preferred the stripper to the harvester, as the cocky chaff was a valuable asset in years such as the present. The men who had nothing but wheat to depend on in this district, on account of the absence of good water on the farm, and railway facilities, had rather a tough battle, and they would do well if they could net a sum equal to the wages earned by an ordinary laborer over an average 10 years. Mr. Wetherall recommended deeper ploughing where stumps were not troublesome.

LONG PRUNING.—Mr. J. Aird then gave a demonstration of "long" pruning the peach. He recommended thinning out laterals rather than shortening them back. In dealing with the top of the tree, he suggested turning one of the laterals, suitably placed, into a leader, rather than cutting the leader to a healthy bud that would grow an unnecessary amount of wood. With the terminal buds left uncut the tree made plenty of short fruit wood. The hon. secretary (Mr. E. W. Chaston) suggested that where the object was to produce fruit long pruning should be tried, and that where a stunted limb or a young tree required to be strengthened short pruning should be the rule.

#### LONG FLAT.

August 31st.—Present: six members and one visitor.

TAINTS IN MILK.—A leaflet on this subject, compiled by Mr. H. J. Apps, of the Department of Agriculture, was read by the secretary and discussed by the members. Mr. Opie thought that cooling was the main factor in ensuring the keeping qualities of milk, and that separating at too low a temperature was a cause of the milk being tainted.

ENSILAGE.—Mr. E. T. Forster expressed the view that it would not pay to ensile any crop that could be made into good hay, as there was too much waste with ensilage. The Hon. Secretary (Mr. H. S. Mann) thought the only advantage that would be gained in making ensilage in this district was that greater bulk of fodder would be obtained.

LOXTON (Average annual rainfall, 12in. to 13in.).

August 27th.—Present: eight members and one visitor.

FALLOWING.—A paper on this subject was read by Mr. Swinburne. He considered that fallowing should be commenced as early as possible after seeding,

and finished by the middle of September. In this district the depth of working should be from 2in. to 3in. on sandhills, and from 3in. to 4in. on the flats. After rain the flats should be cultivated or gone over with heavy harrows, but on no account should the land be worked when dry. Sandhills would not require working if sheep were kept to keep down the weeds. The harrows should be kept going after falls of rain, as this would prevent the ground from setting, and would assist in retaining the moisture. The share plough would pull out more stumps and turn the ground better than a disc implement; but he would use the disc implement for working the fallow back should the ground be dirty, as he considered this could be more easily worked than a tine cultivator. The weeds would grow better on early fallow, and the farmer would then have a better chance of getting his land clean. It was more profitable to have a small quantity of clean fallow than a big area of dirty and badly worked ground. A discussion followed, in which members generally agreed that early fallow was the best, and favored the share plough. There was too much wear on the disc implement in sandy and stumpy country. The fallow should not be allowed to become so dirty that a tine cultivator would not work in it. Members generally did not approve of dry ploughing.

#### MANTUNG.

August 8th.—Present: eight members and one visitor.

**FALLOWING.**—A short paper on this subject by Mr. F. W. Lehman, was read by the Hon. Secretary (Mr. L. Pearce). The writer advised ploughing to a depth of 4in. as soon as possible after seeding, and advocated cultivating in spring, just before harvest. He believed in taking off two crops and then fallowing. This gave the farmer a chance to burn off the stubble every third year, and thus destroy many shoots, before laying the land out to fallow. In sand-hilly country it was unwise to work the land down too fine, with the harrows especially, as this caused drift. He advised keeping a few sheep on the fallow. In the discussion which followed, Mr. A. E. Solly agreed with the paper. Mr. Baker would plough immediately after seeding, and cultivate in spring with a skim plough, and work again before seeding. Mr. Baker preferred the disc cultivator. Mr. Pearce would disc-plough and harrow soon after harvest, let the land lie until after seeding, then share-plough as deep as possible, and would harrow after every rain, and cultivate in spring and before seeding. Mr. W. Stewart also took part.

#### MONARTO SOUTH (Average annual rainfall, 14in. to 15in.).

September 4th.—Present: 14 members and two visitors.

**WORKING FALLOW LAND.**—This subject was dealt with in a short paper by Mr. E. Hartmann, in which he gave the following hints:—Harrow all fallow well, if not immediately after ploughing, then after a rain. Keep sheep on it when dry to keep the weeds down. Cultivate after a rain, working the hard patches first. Never touch it when dry. Use a cultivator (spring tooth). For every foot of ground have three tines, using 5in. or 6in. shares. Cultivate about 2in. deep. Keep the fallow clean of all weeds. Well-worked fallow will retain the moisture better and be easier to handle at seeding time, and it will also give the weeds a better chance to grow by the time one is cultivating for seeding. Never use a skim or disc plough, as fallow worked with these implements will not retain the moisture or sweeten so well. I would sooner cultivate twice than skim plough. I cultivate before drilling, and harrow it down well after. Harrowing the land is necessary where birds are a nuisance. Every farmer should work his fallow well; it will repay him handsomely. In discussing the subject members generally agreed that it was unnecessary to cultivate fallow in spring if it were clear of weeds, and agreed with the writer that all fallow should be cultivated before seeding.

#### PARILLA (Average annual rainfall, 16in. to 17in.).

September 3rd.—Present: 16 members and three visitors.

**CLEARING MALLEE LAND.**—This subject was dealt with in a paper by Mr. E. J. Kerley. Clearing, he said, should be commenced by rolling the scrub in spring.

This would leave ample time for it to dry off well for burning in February. A good burn left the soil in good condition for cultivation and cropping. He recommended the use of the share plough, which was very satisfactory for pulling out the stumps. It did not pay to cart all the small roots off the ground; the drill could be driven with safety over them; but he would take off the larger ones the second year when fallowing, when more draught could be used on the plough. He preferred the share plough to the disc for reducing the young shoots, as the latter implement left more stumps in the ground. If a good burn over the stubble could not be obtained, a fire rake should be used to scorch the shoots. Those remaining could be destroyed with the slasher. Stumps that were of commercial value should be stacked in large heaps. If of no use they should be placed in small stacks and burned. In discussing the paper Mr. C. Moyle considered the practice of placing stumps in large heaps harbored rabbits. Mr. Rush advocated grubbing the larger stumps from the fallow. These, together with the smaller ones, pulled out by the plough, he placed round the mallee shoots and burned, thus killing the shoots at same time. Mr. Gray, a visitor, would reduce shoots where possible with a running fire. Failing this he would use a share plough. He was not in favor of burning stumps, but would save them for fuel, but not in large heaps, as this would harbor rabbits. Messrs. A. J. Stevens, C. S. Foale, J. Tee, W. J. Mitchell, G. Neindorf also favored the share plough; but Mr. C. Millstead preferred the disc implement, which, he said, would work where the share plough would not, and killed more shoots. Mr. H. G. Johnstone found cutting the shoots 6in. from the stump more effective than close cutting. Messrs. P. W. Lewis, W. Shannon, G. E. Gregory, J. J. Foale, S. Hill, and D. McCormack (the two lastnamed gentlemen being visitors from Claypan Bore), also took part in the discussion.

PARRAKIE (Average annual rainfall, 16in. to 17in.).

July 11th.—Present: 10 members.

**SHEEP ON THE FARM.**—Mr. N. J. Goode read a short paper on this subject. Every farm in this district, he said, should carry a flock of 50 breeding ewes all the year round. He suggested the purchase of 50 two-tooth Merino ewes and mating these with a Shropshire ram. From these 45 lambs should be secured, which should be sufficient to supply the household with meat and provide about 15 for sale; these would realise about 25s. per head at six months. The cut of wool from the ewes should realise £15 10s., the total return, including £50 for lambs, being £65 10s. It might be found necessary at times to run sheep on the crops until the end of July, but as a large quantity of oats was grown in this district no reduction in yield would result. In discussing the paper, Mr. Gravestocks also favored Merino ewes, and emphasized the necessity for erecting good fences where the sheep were run. Mr. O'Hara would purchase six-tooth ewes, as they gave a better lamb. He considered the percentage of lambs given by the writer too high. Mr. Dienier would keep not fewer than 100 sheep. Mr. Temby agreed that Merino ewes crossed with a Shropshire ram would be best.

#### WYNARKA.

August 29th.—Present: 13 members and four visitors.

**FARMING IN THE MALLEE.**—An interesting paper was delivered by Mr. J. R. Beck, under the heading "Mistakes I have made." He expressed the view that the disc implement was unsuitable for this country, and under no circumstances would the disc cultivator do such satisfactory work as the share plough. He thought it extravagant to employ seven or eight horses to do the work of shoot-cutting with the disc (one of its strong points of recommendation), when a youth with a slasher would do the work equally as effectively. If the same strength were employed on a stump-jump plough, practically an equal number of shoots would be destroyed and a large number of stumps would be pulled out of the ground. A 17-disc drill was unsuitable in this district on account of the strain occasioned by rough ground, and his experience proved that the stripper was more economical for harvesting. A further matter that required consideration was the somewhat prevalent practice of farmers purchasing old horses, and this he considered a grave mistake.

## SOUTH AND HILLS DISTRICT.

CLARENDON (Average annual rainfall, 33.67in.).

August 6th.

**MIXED FARMING.**—In an address on this subject Mr. F. Shiedow mentioned that he had given up dairying, and was now utilising the greater part of his land for the cultivation of hay and potatoes, with better results financially. Intense culture was advisable. Members discussed the subject at length, and agreed that mixed farming would be found most payable in this district. The Chairman thought it advisable for the farmer to carry sufficient stock to consume the hay crop, and thus improve the land. Samples of King's Early wheat, sown for green feed, were tabled by Mr. Potter. These had been sown early, and had made strong growth. Mr. A. A. Harper mentioned that he had secured very good results from this wheat, but Mr. H. C. Harper said the variety had failed completely on his land last season.

FOREST RANGE (Average annual rainfall, 35in. to 36in.).

September 3rd.—Present: eight members.

**APPLE GROWING.**—A discussion on this subject was initiated by Mr. F. Rowley. Members generally were of the opinion that it was a mistake to grow too many varieties, as there was a good demand for a few choice varieties only. The best apple for export trade was the Jonathan. Buncombe and Rome Beauty were too late for shipment, and the Cleopatra and London Pippin were not suitable for this trade. Worcestershire Pearmain, which was ready for picking 10 or 14 days before the Jonathan, could be profitably included in the orchard. For the local market a wider range was necessary, especially in the case of cooking varieties. There was a good demand for such varieties as Lady Daly, Emperor Alexander, Maiden's Blush, Bedfordshire, and Ann Elizabeth, which bore well. Prince Alfred cracked rather badly, therefore was not recommended. For dessert the early Williams Favorite was ahead of the others, although it only lasted over a season of eight to 10 days. Worcestershire Pearmain would fill the breach till Jonathans were ripe. Jonathans would keep for a month or two, and then the Rome Beauty would be ready. There was some speculation as to whether the Glengyle Beauty would prove better than the Rome Beauty; it had a better appearance, while the flavor was identical. The Rokewood paid well, because of its keeping qualities. It would realise 1s. to 2s. a case more than fruit from the cool stores, because it could be sent around the country, while apples from the cool store had to be used immediately. One noticeable fact with the varieties recommended was that they were all heavy croppers, and would bear eight or 10 cases of fruit, whereas such varieties as Esopus Spitzberg would only yield perhaps one case. Consequently they needed to be planted in better ground. Jonathans especially required good soil and plenty of moisture to make the fruit color well.

GUMERACHA (Average annual rainfall, 33.30in.).

August 3rd.—Present: nine members.

**POTATO-GROWING.**—This subject was dealt with in a paper by Mr. F. Redden. He considered this district excellent for this industry, and mentioned that the local demand for potatoes was increasing. The soil for this crop, he said, should be ploughed two or three months before being planted, and during that period should be frequently worked, so that it would retain moisture. He recommended ploughing to a depth of 9in. The land should have a thick dressing of stable manure. Potato manure was exceptionally good, and bonedust and mineral super. had given good results. Dark, stiff soil, he said, was not adapted to summer planting; loose, sandy land should be selected. It was essential when selecting seed to exercise great care. The seed should be changed every second or third year, and the ground rested after three successive crops. He advised obtaining Snowflake seed from Victoria when a change of seed was required. This variety did exceptionally well in this district. If Carmens or Up-to-Dates were obtained, the round seed would be found best. Seed to be kept from one season to the next should be spread out on wire netting,

raised from the floor of the shed. This would allow the air to circulate round the potatoes, and cause them to become green. If seed were placed on the floor or left in bags it would sprout. Where it was possible to irrigate, planting should be commenced on the first or second week in November. Early planting minimised the danger of frost, and enabled the tubers to be dug before the heavy winter rains were experienced. Where irrigation was not practicable, planting should not be commenced until the middle of January. The rows should be placed about 2ft. apart, and the seed sown every 16in., to a depth of about 5in. or 6in. When the plants almost met in the rows they should be banked up. As soon as the potatoes matured they should be dug, as there was a danger of the moth of the potato worm attacking those nearest the surface, as soon as the soil cracked. Also potatoes would rot if left too long in the ground. If unable to cart them away as quickly as they were dug, he advised storing the surplus, and marketing during July, August, and September, when the prices would probably be higher. He advised producers to sell their potatoes at the Adelaide market, or at their own barns, and not at auction sales. Members discussed the paper at length, and generally agreed with the writer that the Hills growers were handicapped by not having better facilities for transit.

---

HARTLEY (Average annual rainfall, 15in. to 16in.).

August 5th.—Present: 18 members and one visitor.

ERECTING A BROOM-BUSH FENCE.—A short paper was read by Mr. H. Simcock on this subject. A good strainer post should be first placed at each end, buried to a depth of from 3ft. to 4ft., and well rammed. The intermediate posts should be placed about 10ft. apart, and about 2ft. in the ground and 4ft. above. Six wires should be used, three each side of the fence, and the holes bored in the posts a little apart for each pair of wires to enable the brush to go close up to the posts. A trench about 6in. deep, to let in the broom-bush, made the fence stronger. Before being placed between the wires the bush should be cut to the length required. In order to pack it tightly, he used a number of small "S" hooks, and after about 3ft. of broom had been placed between the wires, hooked one of these small hooks on each pair of wires and knocked the broom-bush and the hooks alternately. When the fence was fully packed the top of the bush should be trimmed off. These fences, he said, made admirable break-winds. Members then discussed the paper, and some considered it better to erect iron fences, although it was admitted that the broom-bush made the best garden shelter.

DAIRY COWS.—Mr. J. M. Hudd contributed a paper on this subject. Cows well cared for would pay, especially in districts such as this, where the holdings were small, and it was not necessary to employ labor. He favored the Jersey breed, as it was a small eater, and produced a good quantity of butter. The majority of cows kept, he said, were very poor, and should be disposed of to the butcher. Only pure-bred stock should be tolerated, and for breeding purposes pure-bred bulls from a good milking strain should be used. Six cows kept in good condition would give a bigger return than 12 poor ones. He emphasized the necessity for conserving fodder in good seasons to meet periods of drought. He always cut a good stack of straw when this was available; one stack he had sold for £40. After the harvester had been over the fields, he cut the oaten straw with the binder. Since April last he had fed seven dry cows on this, and they were all in good condition at present. He recommended oats, wheat, barley, and peas (about 4lbs. per day), and pea hay, cut green, as good feed for milch cows. Oaten straw, cocky chaff, barley straw, wheaten straw, mixed with molasses, were also good. Surplus milk could be fed to pigs and fowls with very good results. The writer concluded by giving some figures showing the milk and butter production of different breeds and of some individual cows. In the discussion which followed members agreed that only pure-bred stock should be kept. Some favored the Jersey, whilst others preferred the Shorthorn, as the latter breed was more profitable as a beef cow. Cows required more bulk food than the horse.

REPAIRING FENCES.—Mr. P. Clark read a short paper describing a handy method of repairing fences. He preferred securing the wires with the short pieces of wire in place of using staples, which were likely to be sprung out by stock. He also mentioned a method of repairing strainer posts, and joining broken wires.

**MORPHETT VALE (Average annual rainfall, 23.32in.).**

August 25th.—Present: 11 members and one visitor.

**MIXED FARMING.**—This subject was dealt with in a paper by Mr. E. Perry. He expressed the view that in the past too much attention had been given hay-growing. The time had now come, he said, when landholders would have to turn their attention to other lines, as the export demand for this commodity was falling off. Among activities that could engage their attention were a small flock of sheep and a few dairy cows, which could be combined with pig-raising very profitably. Farmers should make a practice of breeding sufficient horses to keep up the teams, and in his opinion a breeding mare could, with care, be safely worked right up to the time of foaling. Corners of paddocks and other parts of the farm which were otherwise useless could be profitably planted with almond trees. Members generally agreed with the ideas of the writer of the paper, but where it was necessary to hire labor to do the milking it might be found inadvisable to keep cows.

**MORPHETT VALE (Average annual rainfall, 32.32in.).**

September 15th.—Present: nine members.

**FALLOWING.**—Mr. T. Higgins contributed a paper under this heading. He advocated fallowing as soon after seeding as possible. Ploughing should be done to a depth of from 4in. to 4½in. The land should then be cross-harrowed, and when the surface was dry, cultivated to a depth of 3½in. to 3½in., on a fine day. After ½in. rainfall he would cultivate or scarify-harrow to a depth of 2in., and follow immediately by a plain harrowing. If possible, he would harrow after every rain, and then scarify-harrow or cultivate as shallow as possible. On a holding of 150 acres and upwards, he advised always keeping a small team on the fallow, right up to Christmas, and after a rain deferring harvesting for a day or two to put as many teams on as possible, working to a depth of 1½in. only. During January, February, and March of the following year, he would turn the sheep in on the fallow. It was a mistake to plough clayey soil while it was in a wet condition. Cultivating before the drill should be done as shallow as possible, and the drill holes subsequently put to the bottom of the cultivating. Rough fallow had proved as good as best fallow during exceptionally wet years.

**MOUNT COMPASS.**

August 8th.—Present: 12 members and three visitors.

**WINTER PRUNING OF APPLE TREES.**—The following paper was read by Mr. A. J. Hancock:—"The objects of pruning are to modify the natural characteristics of, and at the same time to retain sufficient vigor in, the trees, to ensure even cropping and even-sized fruits. After three or four years hard pruning of the newly planted trees, if a great amount of strong wood growth is produced, it is advisable to allow longer pieces of the previous season's growth on the leaders to remain, with the object of encouraging the production of fruit. Great judgment is required to attain this end, and perhaps the pruner does not attain his object the first season; but by closely watching the results of his work, he is enabled to form an idea of how much wood to leave on the leaders, and thus get a more evenly balanced head on the strong root system laid down by the first three or four years' hard cutting back. My experience has been that until this object is gained, one will never get the best results. The trees will turn out a prolific crop of undersized fruits one season and perhaps a few oversized the next. One will probably get a lot of apples under 2½in., and the biggest portion of the crop will not average 2½in. Consequently it is of little value, except that a limited quantity may be disposed of to make jam and jelly. It is necessary in different localities to modify the methods of pruning, and also to closely watch the results on the trees. Jonathans have been my most difficult trees to manage. I find that if the young laterals are pruned back, they only die back to the main limbs, and on the other hand, if left (no matter how unsightly they seem), and the second year pruned back to the end of the previous season's growth, the spurs will in most instances develop along the laterals. These can afterwards be shortened in to any desired length without injury. With the *Rome Beauty* variety (although of an entirely different type of tree), very nearly the same treatment of laterals is required." In the discussion that followed members strongly advised spraying as a preventive against codlin moth. Except where

second-year growths were being cut, pruning should not cause the wood to die back when the tree was dormant. Mr. Jacobs was of the opinion that generally in this district too much wood was left on the trees. The chairman (Mr. Peters) mentioned that he had been following the instructions of the Horticultural Instructor (Mr. Geo. Quinn) in connection with his trees, and for several years he had secured good crops. Mr. Hancock thought spraying at the present time with from 1lb. to 2lbs. bluestone in 40galls. of soapy water would check *Fusicladium*. August was a good month for pruning and root grafting.

**VEGETABLES.**—Mr. D. Wright advised planting the following vegetables during September—Carrots and parsnips in the swamps, celery and tomato seed in boxes, beans, onions, potatoes, beetroot in the lighter soils. Localities which were subject to severe frosts should be avoided. Mr. Jacobs advised germinating celery and tomato seed between damp bags placed on the manure heap.

#### MYPONGA.

June 10th.—Present: 13 members and several visitors.

**EXPERIMENTS WITH POTATOES.**—The meeting was held at the homestead of the secretary (Mr. F. Muller), and the following manurial test plots were partly dug, with the results shown. The variety of the potato was Snowflake, sown in virgin soil—

| Total .....       | 8                                                                      | 11 | 0  | 26 | 7                              | 19 | 0  | 22 | 6                                                   | 6  | 3  | 2  | 7                                                   | 8  | 1  | 12 |

Other varieties tested, such as Up-to-Dates, Carmens, and Excelsiors, were found to have germinated unevenly, and Carmens were the best of these. Cut seed had proved superior to whole seed.

**PORT ELLIOT, August 15th.**—Present: nine members. A discussion followed the reading of an article on "Influence of Food on Milk," and several members advocated crushed oats and chaff as the most economical dry feed for this district. For green feed maize and lucerne were the best.

**STRATHALBYN, September 1st.**—A member contributed a paper on the co-operative purchase of implements, and this was discussed at considerable length by those present.

## SOUTH-EAST DISTRICT.

## COONAWARRA.

August 4th.—Present: eight members and one visitor.

**GROWING SEED WHEAT.**—The following paper on this subject was read by Mr. J. L. McBain:—He said "Obtain seed true to name and free from all impurities. Before pickling run it through a winnower with a shot-hole sieve, being sure that the machine is doing its work properly, so that there is nothing left in the seed to obstruct it in its course through the drill. Prepare a piece of clean, even ground large enough to return more than enough for the coming seedling. Pickle the grain in 1½ lbs. bluestone to 10 galls. of water. At least three days before sowing. If pickling in a cask, shoot the seed into a bran bag in the pickle, then stir, allowing the pickle to pass freely through the seed for a few minutes. Following this drain the wheat and shoot it into clean bags. If on a floor see that the grain is all saturated. Before commencing to sow see that the drill is thoroughly clean, not forgetting the manure box. Sow not later than the third week in May, at the rate of three-quarters of a bushel of seed and lewt. manure per acre. Weigh the seed before pickling. Let the crop thoroughly ripen before harvesting; when harvested run the grain through a winnower. Repeat this practice every year." A useful discussion followed the reading of this paper.

**MILLICENT** (Average annual rainfall, 29.25in.).

August 11th.—Present: seven members.

**RABBIT-POISONING.**—In discussing this subject Mr. Bowering expressed the view that the best time to deal with this pest was in the breeding season, when the young rabbit could be destroyed in the burrows. Mr. Serle would securely net the holding, and then trap inside.

**RYE GRASS.**—In reply to a question Mr. Holzgreffe recommended sowing rye grass after the first rains. He mentioned that better growth had been secured on land that had been well trodden down, and advised putting ½ bush. of Cape barley per acre with the rye grass. Members also discussed the necessity for breeding from the best stock only, and the matter of fallowing. In connection with the latter Mr. Serle mentioned that he had worked one paddock for seven years in succession, and the last crop he took off averaged 32 bush. to the acre.

**KALANGADOO, September 12th.**—**CROSSBRED SHEEP.**—A number of samples of comeback wool were tabled, and examined by members. Mr. Kennedy mentioned the following matings, which members agreed constituted a Comeback sheep:—A—Longwool ram, Merino ewe—issue, half-bred ewe; B—Half-bred ewe, Longwool ram—issue, three-quarter-bred ewe; C—Three-quarter-bred ewe, Merino ram—issue, half-bred ewe, balance; D—Half-bred ewe, Merino ram—issue, "Comeback." [The Director of Agriculture comments on the above as follows:—"I agree with A, B, and D, but not with C, which does not, in my opinion, constitute a half-bred ewe.—Ed.]

**SANDALWOOD, August 6th.**—The inaugural meeting of this Branch was held at the residence of Mr. A. E. M. Lovell (hon. secretary). Mr. H. J. Finnis, of the Agricultural Department, delivered an address on the organization and aims of the Agricultural Bureau.

**SANDALWOOD, September 12th.**—**MANAGEMENT OF TEAMS.**—Mr. J. E. Hood read a short paper on this subject. When carting with a fresh team, he said, the loads should be light at first, and gradually increased in weight as the horses settled down to their work. He made it a practice when moving off with a load to first stand all the animals up in the collars. The weight would then be taken by the whole of the team together and gradually. Before and after an extra heavy pull the team should always be given a brief spell. He deprecated the practice of shouting and brandishing the whip. New collars should fit fairly tight. He recommended applying wattle-bark liquid at midday and evening as a preventive against sore shoulders. Drivers would find that they would get more out of their teams if properly handled and cared for.

## INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

## STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"L. H. F.," Moorook, had mare which suffered from intermittent colic with shivering, and eventually died. He asks cause and also treatment for other horses which have been off color.

Reply—Being isolated from aid you will find "Law's Farmers' Veterinary Adviser" helpful, and more so "Diseases of Horses," U.S.A. Agricultural Bureau. The intermittent attacks the mare had were due to the extension of patches of inflammation originally set up by the blood worms you describe; death followed peritonitis, which set in after the bowel burst, probably on the fourth day. The lump on the stomach was a worm cyst. The reason the bran and oil came away was that it floated over the other bowel contents, which were impacted. The quantity of sand likely to be fatal depends entirely on the individual horse, and ranges from a peck to a bagful. The amount of fluid you found was peritoneal effusion; ordinarily the fluid contents of the bowels are about 7galls. in the blind gut, like pea soup. Your trouble with the other horses is a very rare one these times, namely, that they are getting too much to eat. You would find they would do better on less, say three feeds, and should have 10 drops tincture nux vomica morning and evening for a fortnight or so, just put on the tongue.

"F. M.," Myponga, asks treatment for cow which got bogged in swamp and after being got out became partially paralysed, with pain in shoulders.

Reply—Rub in hot mustard oil over affected parts; mix daily with food 1 dram powdered nux vomica, 1 dram sulphate of-iron,  $\frac{1}{2}$ oz. flowers of sulphur, with sufficient molasses to allow of thorough mixing.

"J. J. M." asks treatment for cow suffering from growth on top corner of eyeball; it is increasing in size.

Reply—The growth is not a cancer, but the result of an injury such as an oat seed or barley awn. There is no danger in using the milk. It would be well to get  $\frac{1}{2}$  grain of cocaine and place between the eyelids, this will dissolve in the tears in about five minutes, and deprive the eye of feeling; it can

then be thoroughly examined, and any foreign body detected can be removed. The growth should be lightly touched with caustic and a cloth hung over the eye, kept wet with half water and half methylated spirit with a few drops of tincture arnica. This should be wetted several times a day.

"P. P. P.," Clare, has valuable draught mare which week off foaling had swelling in off hind leg. She shivers and seems generally off. Became bad after being turned into crop affected by drought.

Reply—The symptoms are alarming, but not dangerous. The attack is lymphangitis, which often affects mares heavy in foal, especially after a change of feed such as described. Give her steady exercise for an hour or two a day, no matter how lame she seems at the start. Also twice a day in a sloppy bran mash a heaped teaspoonful of saltpetre for a few days, once a day in feed 10 drops of tincture arsenicum, and if leg is very hot and painful, foment with hot water, taking care to dry well after. The swelling will probably involve the udder and belly, but there is no need for alarm; it will disappear after foaling.

"G. W." asks advice concerning blood stallion which refuses wet mares.

Reply—Many blood horses have this peculiarity, and, annoying as it is from an owner's point of view, little can be done. Try stimulating food, old beans if you can get them. Drugs are not recommended, but a German preparation called Yohinbin, obtainable with instructions at the Adelaide drug houses, has some supporters.

"G. McC.," Inman Valley, seeks cure for warts on mare's cheek; appeared two years ago and are spreading.

Reply—As this has been in existence two years it is probably a papillomatous growth for which the knife would be the best treatment. Failing this, it should be painted with a little solution made of one part pure iodine dissolved in four parts pure carbolic acid. As soon as this is dry it should be thickly smeared with Venice turpentine and covered with oiled rag or paper and left on for a week, then washed off with a mixture of half methylated spirits and half turpentine and treatment renewed. This will have to be done about four times, when the growth will possibly be fit to clean out by the roots, it should then be painted daily with one part tinct. thuya in 10 parts methylated spirit.

"A. G. I.," Waikerie, asks treatment for mare which has occasionally small sores and hard lumps on belly and is rubbing hair off neck.

Reply—The blotches are due to microscopic worms in the blood, and the rubbing probably to similar parasites in the skin. Benefit will follow the use of one dessertspoon of Fowler's solution of arsenic once daily in the food for a month; also a similar dose of sulphur once daily for the same period, and the mane should be dressed once a day for a week with one part benzine in any common oil five parts, rubbed in with an oily rag.

"G. B." asks treatment for cow suffering from redwater after calving.

Reply—If she has not yet had a pound of Epsom salts give it to her in a quart of beer or half-pint of pinkie. Then twice a day till better, 1dr. powdered nux vomica, 1dr. saccharated ferro-carbonate given in a little gruel. She will probably recover in a few days.

"C. J. F. D." asks treatment for dog suffering from mange.

Reply—There are different kinds of mange, some of which are very difficult to cure. If the dog is valuable it would be better to send it to a qualified

veterinary surgeon in Adelaide for treatment, if not, it would probably be most economical to destroy it. However, if it is desired to treat it, try five drops tr. arsenicum morning and evening on the tongue, and dress once daily with a solution of 6½ grs. of chinosol in a pint of water.

"A. H. T.," Cleve, asks if it is safe to give Fowler's solution of arsenic to mares in foal.

Reply—Fowler's solution of arsenic is not a patent medicine, it is the ordinary liquor arsenicalis B.P., and contains 4 grs. of arsenious acid to the fluid ounce. It is necessary to use judgment in giving to mares in foal, but, as a rule, is beneficial. Sucking foals get it through the milk; if given to them, a teaspoonful would be a dose. Arsenic in any form is not to be carelessly handled; but this form enables it to be accurately measured easily, and is readily absorbed.

"J. S.," Tumby Bay, asks when and how to ring bulls.

Reply—Bulls are best rung as yearlings; the ring is copper and hinged with a screw to fix it; it is obtainable at any hardware store. A usual way of ringing is to tie the bull up, hold the nostrils with finger and thumb, and pierce the gristle between the nostrils with a big bag needle or small knife; if using the latter mind it does not slip if he jumps; enlarge the hole by passing a steel through, then put the sharp end of the ring through, close the ring and screw up; no particular dressing is required, but a little grease or healing ointment such as boracic may be used if desired.

"J. V. K.," Serviceton, asks treatment for (1) heifer which is weak in hind legs, with lameness; she trembles if moved quickly, and dung is black and hard; and (2) for cow which has injury to eye from chaff.

Reply—The symptoms are like those of yacca poisoning or auto-intoxication. Treatment—(1) Give 1 dr. powdered nux vomica and 1 dr. sulphate of iron twice daily in 1 lb. molasses and water. (2) If the front of the eye (cornea) is ulcerated nothing will clear it. If not, dust in a pinch of dry boracic acid twice a week.

#### HORTICULTURE.

A member of the Tarcowie Agricultural Bureau seeks advice concerning apricot tree which was pruned in July and since has been bleeding and gumming.

Mr. George Quinn, Horticultural Instructor, replies—The bleeding or exudation of sap of the apricot tree may be due to the extraordinarily dry season causing a movement of crude sap to begin earlier than usual. It is possible the exuded sap has been attacked by fungi or bacteria, and the continuance of the flow intensified thereby. I suggest you cut the limbs back an inch or two below the gumming wounds and immediately apply to the fresh cuts a coating of thick lead paint. If this is not available, a thick coating of limewash, into which a little bluestone has been dissolved, or failing this a thin coating of tar. The paint or tar should only cover the woody fibres of the wound and not allowed to run over the bark.

"C. J. D.," Penola, has been in the habit of digging in manure round his fruit trees each year, with the result that there is a mound of earth round each. He asks (1) Is this detrimental, and (2) Is it injurious to prune any fruit tree when commencing to bud.

Mr. Quinn replies—(1) The mound of soil caused by digging in manure around the stems of the fruit trees should be reduced to the normal height

of the surface of the ground without delay by spreading the surplus out between the trees. In future, dig the manure into the land outside the spread of the branches where the feeding roots are usually located, as this encourages them to spread into a wider foraging area. (2) If the trees need pruning, it is better to do it when they are coming into bloom than to leave them uncut. In the case of stone fruits, such as peaches and apricots, it is not at all undesirable to prune at the stage mentioned.

"R. C." forwards cabbage plants infested with caterpillars and asks how best pest may be got rid of.

Mr. Quinn replies—The cabbage plants, as you are probably aware, are attacked by the caterpillars of the diamond-backed cabbage moth (*Plutella cruciferarum*), which is a pest on most cruciferous plants, such as the cabbage and cauliflower, and even garden wallflowers and stocks under certain climatic conditions, such as a long drawn-out dry autumn season or an early rainless summer such as is now being experienced. These caterpillars are very active and destructive, eating away the green chlorophyll-bearing cells leaving the transparent epidermal skin to dry and break, thus showing complete holes in the leaves. The pest is easily combated if taken in the early stages of the infection, more particularly before the leaves begin to form hearts in the cabbages or "flowers" in the cauliflowers. Being a chewer of the surface tissues the caterpillars are then easily poisoned by spraying the foliage with a weak arsenical compound such as arsenate of lead. When the hearts of the plants begin to close up there is a fear of the poison collecting in the folds and being absorbed by the consumers of the vegetables, although with the thorough washing such foliage usually undergoes prior to being cooked, this danger is probably more imaginary than real. These caterpillars may also be killed by contact insecticides such as kerosine emulsion or resin wash, but, though harmless, the constituents of these washes have distasteful flavors for the human palate unless a very thorough washing process is adopted before eating the vegetables. Mr. C. French, the late Government Entomologist of Victoria, advises the use of tar water, made by boiling 1lb. of tar in 2galls. of rainwater and then diluting it with 100galls. of soft water before spraying it upon the plants. Usually, with this as with other plant pests, prevention is better than cure, and cure when the advanced stages are reached becomes impossible unless at the same time the host plants are sacrificed. Frequently this and the cabbage blight (aphis) obtain a start upon the plants in the densely packed seedbed, and by dipping the plants in an insecticide before setting them out the pest is "nipped in the bud," so to speak. On plants such as you sent me I should certainly advise trying the effect of these sprays, and at the same time giving the plants a little stimulant in the shape of a dressing of nitrate of soda or sulphate of ammonia washed into the roots with an irrigation.

"H.B." gives description of sickly citrus trees, and asks for advice as to treatment.

Mr. Quinn states—From the description given of the citrus trees I think it likely they are affected by what is commonly called collar rot, or *Mal de gomma* (as known to the Italians). If this is so it is a defect which has become world wide in significance to orange and lemon growers, being known in the Azores, Florida, Italy, California, and Australia as a common source of destruction in citrus groves. Symptoms of the disease.—This disease is usually first noted in a tree by an unusually heavy blooming, and often setting of

fruits followed by a pale color gradually coming in the foliage, which later begins to fall away from the tips of the shoots first, but gradually from all parts of the tree. The cause of this is injury to the bark at the ground line, where generally small beads of gum exude, first exuding from cracks in the bark, which soon turns reddish-brown over the declining patches. If cut away with a knife often the dead bark is in an irregularly shaped patch, gradually spreading around the stem. As this wound by degrees cuts off the sap layer, the symptoms previously described are noted upon the upper parts of the tree. This defect appears to be either primarily caused by a fungus called by the Italian investigator Briosi *Fusarium limonis*, or greatly aggravated thereby; but apparently unless the conditions are made favorable it does not strike into the tree. The favorable conditions appear to be of a varying character. Stocks.—In the first place the stocks on which the trees are worked have varying powers of resistance. The lemon and sweet orange seedlings do not appear to withstand the conditions so well as the Seville or sour orange seedling. Depth of Planting.—If the trees are planted deeply, and the wet soil banks high above the crown of the roots, or irrigation water soaks against the stems. Drainage.—Bad drainage about the root system affects the general constitution of the tree, and renders it liable to weakness. Mechanical injuries.—This disease appears to be transmissible through the medium of implements and tools, and bruises or wounds made about the soil line appear to set up a state of liability to contract the disease if they do not actually represent infection by means of the injuries from tools. Remedies.—Besides the above (which are warnings towards prevention), when the collar rot does attack the trees the best localised treatment recorded to stay its ravages appear to be found in carefully cutting away the dead and declining tissue with clean, sharp tools. All the scrapings should be carefully collected and burnt, and the dried and wounded surfaces painted completely with carbolic acid solution made of equal parts crude acid and water. White lead paint, and even coal tar have been used successfully. If the wound extends very far around the stem, after applying one of these dressings, cover it with a bandage of bagging, a plaster of clay, or other material calculated to keep the drying wind and sun from the bark. If the tops of the trees have begun to die back, cut away all dead and dying wood down to where healthy shoots arise, and keep the tree supplied with water in increasing quantities, as the new growth emerges. A dressing of soluble fertilisers, such as sulphate of ammonia or nitrate of soda, with which may be mixed sulphate of potash and superphosphate at the rate of 1lb. of each of the two first-named, and 3lbs. to 5lbs. of the superphosphate to a large tree, may be given. These may be placed in the irrigation rings or furrows, and soaked in with the water. After these operations stir the surface of the soil into a deep, dry, loose layer, and if convenient cover it out beyond the spread of the foliage, but not against the tree's stem, with an inch of loose manure or farmyard litter.

#### ARSENICAL POISONING OF WEEDS AND WHITE ANTS.

In response to an inquiry the following information, supplied by the Railway Department, in regard to the use of arsenic for poisoning white ants and weeds, is published:—

*Mixing and Handling.*—Care must be taken that the use of arsenic is so conducted as to prevent the possibility of injury to human or animal life resulting therefrom. No tank which has contained arsenic should be used

for the storage of water, and all vessels employed in connection with poisoning operations should be marked "Poison," covered, and used for no other purpose. The material should be prepared only in such quantities as can be immediately used, and when the vessels are finished with on any individual occasion they should be thoroughly cleansed and stored in a safe place until again required. The dissolving of arsenic by boiling in water should in no circumstances be attempted; the work should be carried out by mixing the arsenic with caustic soda. Care should be exercised so that those engaged in the work shall not be exposed to the necessity of coming into contact with the arsenical solution, either by handling it for transfer or after it has been distributed upon the weeds or timber.

*For White Ants.*—Where timber is found to be attacked by white ants, or their presence suspected, the solution to be employed should be prepared and applied in the following manner:—To every 56lbs. of arsenic add 20lbs. of powdered caustic soda and mix in 15galls. of water, stirring thoroughly. Take a sound cask, remove the head, and clean thoroughly. Put in the water, then add the soda (usually supplied in tins, which should not be opened until required). The soda will dissolve, and in a few minutes produce great heat. Add the arsenic at once and cover the top of the cask with bags. In about a quarter of an hour remove the bags and stir thoroughly for two minutes. The result is a strong solution containing nearly 60ozs. of arsenic per gallon. When used, it should, as a rule, be diluted with 20 times its bulk of water, but in special cases a greater strength may be employed. On applying this to piles, girders, and other large scantlings,  $\frac{1}{2}$ in. auger holes should be bored into the heart of the timber and the solution poured in. The holes should be plugged with turned hardwood plugs to keep out dirt and damp. The plugs could be removed periodically and the holes tested to see whether they are free from dirt, if not they should be refilled with the solution. All joints should be flushed with it. When fence posts are attacked the earth should be cleared away from the foot, the galleries raked out with a piece of hoop-iron, and the solution applied with a stiff brush and poured over the top.

*For Destroying Weeds.*—To every 56lbs. of arsenic add 20lbs. of powdered caustic soda and mix in 15galls. of water, stirring thoroughly; add 1,033galls. of water, which will reduce the liquid to the correct strength and will be sufficient to sprinkle 40 chains long by 11ft. wide. The solution can be used to most advantage when the weeds are young, because then every plant is exposed to its action. When used on rank growth the large leaves take most of the solution, and the smaller growth underneath is not properly destroyed, because the solution does not get to its roots. For rank growth more of the solution is required to make clean work, and it will be necessary to apply the solution a second time after the large weeds have withered off. Such poisoning must be restricted to places where there is no danger of the arsenic being washed down by rains and so injuriously affecting water likely to be used for man or beast.

#### RHODES GRASS.

The following description of Rhodes grass is supplied by Mr. Spafford (Superintendent Experimental Work) to an inquirer:—This grass is essentially a summer-growing plant, and as such, in a climate like ours, it is only possible to make the most of it by treating it as an irrigated crop. In your district this is quite necessary. There is no comparison between this plant and lucerne, for anyone who has a fair supply of water for irrigating purposes; but it will

produce a good quantity of feed of fair quality with little water. In this respect it is even a good deal superior to *Paspalum dilatatum*, another fodder plant not requiring very much water to supply fair feed in the summer. In habit of growth this plant resembles the common buffalo grass, in that it sends out "runners" along the surface of the soil, and every node that touches the ground takes root. In this way it does not take long to cover the whole surface of the ground. As it approaches flowering it grows very upright, and under good conditions will stand 3ft. high and very thick at that. Where it is cut and fed to stock it is possible during the season to get two such cuts, and a very fair picking for stock following the second cut, this, of course with a watering in the spring and one after each cut. Makes fair hay so long as not left to get too tough before cutting, and in the green state is eaten by all forms of live stock. If roots are planted, they should be in rows 3ft. apart and 2ft. to 3ft. apart in the rows. All nurserymen sell these plants for about 15s. per 1,000. If seed is sown, it should be at the rate of 10lbs. per acre, and will cost about 2s. per pound. As the seed is very small, the seedbed for it must be in a very fine state of tilth, to ensure anything like a decent germination. It might produce enough feed on some of your sandhills without irrigation to pay for the planting of it, but you must consider it as a crop that needs water in any district but those with certain spring and summer rains.

## ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Tuesday, October 13th. The Chairman (Mr. G. R. Laffer, M.P.) presided, and there were also present the Principal of the Roseworthy Agricultural College (Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S.), the Chief Inspector of Stock (Mr. T. H. Williams), Messrs. A. M. Dawkins, C. J. Tuckwell, J. Miller, Col. Rowell, and H. J. Finnis (Acting Secretary).

*Col. J. Rowell.*—The Chairman congratulated Col. Rowell on his recovery and welcomed him back to the Board meetings.

*Wool-Classing Demonstrations for Farmers.*—The Acting Secretary mentioned that the Gladstone Branch some time ago asked that arrangements should be made, if possible, for the School of Mines Wool Instructor (Mr. Henshaw Jackson) to visit the rural districts during the shearing season and give practical wool-classing demonstrations for the benefit of the farmers. The request was brought under the notice of the Council of the School of Mines, which stated that it was of the opinion that a further diffusion of knowledge on wool-classing among the farmers was desirable, and would materially benefit the State. The Council was willing to arrange for an extension of the work of the school's wool-classing department in the direction indicated. The extra work entailed would require the appointment of an assistant instructor, whose salary and travelling expenses would necessitate an increase

to the school's vote of £350 per annum. That report was considered in Cabinet in connection with the Estimates, and subsequently returned to the Agricultural Department from the Education Department, with the intimation that present circumstances had prevented any increase of expenditure being approved. In the circumstances the Board agreed that it would be unwise to press the matter further.

*Improving Milch Cows.*—A request from the Port Elliot Branch that the Board should take up the question of encouraging the stockowners to keep a better class of bulls was considered. It was stated that the dairy cows trucked south in consequence of the drought in the North appeared to be poorly bred. Mr. Williams said there certainly could not be a finer opportunity than the present to improve the class of animals kept. It was pleasing to know that 3,000 bulls of a nondescript character had passed through the Abattoirs recently. Generally speaking the bulls which had hitherto been used were a disgrace to the State. The difficulty would now be to obtain sufficient animals of the right type. Possibly they might be secured from New South Wales and Victoria. As a substantial step towards the desired improvement, he suggested the formation of boards consisting of, say, three members, one of whom would be the Chairman of the local Branch of the Bureau, in the different districts to examine all bulls, and have castrated those which failed to come up to the standard. That would necessitate the passing of fresh legislation. Mr. Tuckwell asserted that not half of the farmers had pure-bred bulls, notwithstanding the fact that they had been urged again and again by the officers of the department to use pure bulls, whatever their cows might be. Under existing conditions nobody's cows were safe from the mongrel animals which were too frequently allowed to roam over the country. Mr. Colebatch thought desirable bulls would be obtainable, but doubted whether the farmers had the money to pay the prices demanded for them. Ultimately the Board decided to send the letter to the Minister with a strong recommendation that, in view of the favorable opportunity for effecting a decided improvement, reports on the subject should be obtained from the Stock Department and from the Government Dairy Expert.

*Fruit-Packing.*—It was resolved to forward to the South Australian Fruit-growers and Market Gardeners' Association, with a request for an expression of opinion on the subject, the following resolution from the Cherry Gardens Branch of the Bureau:—"That the Advisory Board be requested to urge upon the Minister of Agriculture the advisableness of securing the services of an expert packer to give demonstrations throughout the fruit-growing centres of the packs most suitable for the oversea markets."

*Seed Wheat.*—A request from the Conference of the Hills Branches that the Board should bring under the notice of all the Branches in the wheat-growing areas the matter of keeping the different varieties of grain separate, and distinctly branding the bags, so that the wheat distributed among the farmers in the drought-stricken districts for next season's seeding should be true to name and type, was considered, together with a similarly worded resolution from the Wepowie Branch, and at the instance of Mr. Colebatch it was decided to circularise the various Branches accordingly.

*Postal Carriage of Fruit.*—A letter was received from the Department of Posts and Telegraphs, South Africa, enclosing the regulations and rates connected with the postal carriage of perishable produce. It was stated that the number of parcels posted during the past 12 months was 25,000, repre-

senting a value in postage stamps of £900. Owing chiefly to recent necessarily rigid curtailment of the class of article permissible at the Agricultural rate, postings were decreasing at the rate of 3 per cent. per annum. The system was worked at a loss in South Africa, chiefly on account of the costly maintenance of long post cart, horse, and native carrier routes. Instances of damage to the contents of mail bags caused by such articles as fruit, eggs, and butter, were frequent.

*Congress and Hills Conference.*—Mr. A. M. Dawkins briefly reported on the proceedings of the Annual Congress and Conference of Hills Branches. In connection with the former it was mentioned that the amount of £9 8s. 11d. had been handed to the Mayor's Patriotic Fund as a result of the collection made at the Congress.

*New Branch.*—Approval was given to the formation of a new Branch at Koonibba (hundred of Catt), with the following gentlemen as members:—Rev. Weebusch, A. Schmidt, S. Rudolph, A. Moody, J. Fogo, E. Gersch, G. E. F. Schultz, F. Hantke, O. Hantke, H. Schroeder, R. Schultz, P. H. Schultz, M. Linke, R. Temme.

*New Members.*—The following gentlemen were admitted as members of the Branches shown, viz.:—Mundoora—M. Dee; Wirrabara—W. Sizer, W. J. Ragless, R. Quinn, B. C. Joppich; Carrow—H. Byrne, L. McBride; Booleroo Centre—W. Shepard; Berri—H. B. Moss; Coonawarra—R. C. Lear, E. W. Clayfield; Artherton—D. M. McKenzie; Morchard—G. W. Gregory, T. H. Parsons, W. H. Muller; Mount Remarkable—W. Barrie; Long Flat—G. B. Kuchel, T. R. Stecker; Miltalie—J. A. L. Ramsey; Wynarka—R. Harrington, T. Yates; Borrika—L. E. Mansfield, T. Bishop; Strathalbyn—E. Hill, J. J. Lee; Mangalo—W. N. Knight, F. W. Masters, L. J. Jackson; Bute—K. Pontifex, R. Neville, N. H. Eschner; Kingston-on-Murray—F. Foord; Cherry Gardens—A. J. Mildwatwers; Yadnarie—G. E. Francis, A. W. Smart; Geranium—C. Toseland; Myponga—J. E. Hender, F. Eatts; Elbow Hill—W. Story; Clare—I. C. Radford, S. Pascoe, J. Edwards, C. E. Birks; Beetaloo Valley—J. Flavel; Leighton—S. S. Sanderson; Inman Valley—A. G. Wallmann, S. G. Grosvenor, G. H. J. Meyer; Milang—B. Blackwell; Sandalwood—S. H. R. Lovell, W. R. Page; Wirrabara—C. E. Kemp; Green Patch—W. J. Hooking; Mount Barker—F. W. Smith, C. Edwards, V. Henderson, J. P. Hoskin; Narridy—W. Wotzke, G. Smith, H. Threadgold, T. Brown; Millicent—J. C. A. Nitschke, G. E. Fensom; Renmark—H. Skelsey; Booleroo Centre—J. J. Arthur, E. C. Smith; Naracoorte—W. C. Buck; Riverton—H. Nield, E. Kelley; Tintinara—A. Woolford, D. T. Kennedy, N. Bainger; Parilla—J. Northey; Wilkawatt—W. R. Neville; Berri—R. Gurran; Mallala—D. A. Moody; Bute—J. L. Davis, D. Walton, E. W. Schroeter; Narrung—J. W. Bottrill; Strathalbyn—F. Abbott; Kingston-on-Murray—A. Watchel, F. Setterberg, J. Smith.

## EYRE'S PENINSULA.

### VISIT BY DIRECTOR OF AGRICULTURE.

#### PROPOSED EXPERIMENTAL FARM.

One of the first tasks undertaken by Professor Perkins upon his appointment as Director of Agriculture was a comprehensive tour of that vast tract of agricultural land comprised in Eyre's Peninsula. Accompanied by the Secretary of the Advisory Board (Mr. G. G. Nicholls) the Director left Port Lincoln on September 25th and motored to Fowler's Bay. Meetings of the several Branches of the Agricultural Bureau were held en route, and the Director discussed with farmers those matters upon which his advice was desired. From Fowler's Bay the country between Cape Thevenard and Minnipa Hill was inspected, including several hundreds about to be opened for application. At Minnipa, Professor Perkins selected a site for the Eyre's Peninsula Experiment Farm, which it is proposed shall ultimately become a centre for the work of the Department of Agriculture on the Peninsula. This is to be linked up with experimental plots in various parts of the country wherever circumstances warrant such work being done. These plots will be placed on the holdings of private farmers, who will do the necessary work under the supervision and at the cost of the Department. Proceeding to Wudinna, the hundred of that name was examined, and also Yaninee, Pygery, Perlubie, Wannamana, Kappa-koola, and Warramboo. From the Hundred of Shannon the journey was continued through Stokes, Koppio, Hutchison, Louth, and Wanilla to Port Lincoln. From Port Lincoln to Cowell, including the hill country west of the coastal plain, the several types of country were inspected and the Bureau Branches were visited. Altogether 19 meetings were addressed by the Director and the Secretary to the Advisory Board. A new Branch of the Bureau was formed and preliminary arrangements were made for establishing several others. Upon returning to Adelaide Professor Perkins said, that although he had seen the country at its worst—under conditions of drought—he had been much impressed by the large extent of good arable land settled and being made available for agricultural occupation.

D. F. LAURIE, Poultry Expert and Lecturer.

## REPORT FOR MONTH OF OCTOBER, 1914.

The weather has throughout the month been abnormally dry and warm. Record temperatures (106° shade) have been experienced. Rainfall meagre, total .05in. The health of the birds has been good. Four deaths occurred in Section I. and one in Section III. Egg-production is still satisfactory. Some good scores are expected, especially in the single pen sections. Broodiness is rife. In Section I. there were 17; in Section III., 2; and in Section IV., 43. In Section IV., 21 cases are among the birds disqualified for short-weight eggs, but which are still under observation. Greenfood supplies are ample. Further crops of lucerne are being sown. During the month a large number of visitors attended. On the occasion of a special visit 115 were present. The various pens in the competition were the subject of much comment. The chief interest is centred in the single testing sections; the full value of this method is generally recognized.

D. F. LAURIE, Poultry Expert and Lecturer.

## THE AGRICULTURAL BUREAU.

### THE TWENTY-SIXTH ANNUAL CONGRESS.

*(Continued from page 304.)*

#### WEDNESDAY, SEPTEMBER 9th.

Congress resumed at 9.30 a.m. on Wednesday, September 9th. Mr. C. E. Birks (Advisory Board) presided.

#### MIXED FARMING.

The following paper on "Mixed Farming" was read by Mr. A. I. McEwin (Blyth):—

Although the title of my paper would permit of the treatment of every class of production practicable in our large wheat areas, I do not intend to recommend farmers to go in for everything that can be raised on a farm. If one has too many irons in the fire it is difficult to keep them all hot. In my opinion it is not worth while for a man to be pottering around with a few fowls while a team of eight horses is idle in the stable. Fowls are a necessary item about a farm, just as a cow is; and one cow properly kept is better than three starved, and is less trouble. There should be pigs enough to consume the waste. These are stock that will be about any well-managed farm. But I wish to particularly advocate wheat-growing on the third-year system and stock-raising as against wheat only on the each alternate year system, or "wheat and fallow," "wheat and fallow." Further, I deal more particularly with land under a 16in. to 20in. rainfall, which is about the average on all the good plain country north and north-west of Adelaide.

Since the advent of artificial manures, which have been generally used since 1900, farming has been a much more profitable undertaking than previously, and land that was almost going out of use for wheat-growing is now yielding handsome crops, and also has treble the carrying capacity for stock. Land has also increased in value to three times what it was then worth. The original holder has a good proposition, but the present buyer has not much margin to come and go on. Not only is land at a high value, but everything else is correspondingly high—labor, machinery, taxes, and all the farmer needs to buy. Wheat—the largest commodity he has to sell—and hay are only very normal, and wheatgrowers would welcome a rise of 9d.

a bushel on the prices realised during the last few years. Fat stock have been at a premium just lately, but that is on account of the season, and is of benefit only to the few.

#### RETURNS FROM WHEAT AND FALLOW ONLY.

My experience is that it takes a 16bush. crop to make farming pay on land valued at from £8 to £10 an acre, and I make this up as follows :—

For wheat grown on the alternate system, 5 per cent. on the value of the land, 8s. per acre, one crop in two years makes 16s. For fallowing, ploughing, 6s.; cultivating twice, 4s.; harrowing three times, 2s. At seed time—Seeding, cultivating, 2s.; drilling, 2s.; harrowing, 8d.; seed wheat, 4s. 6d.; manure, 5s. Harvesting with the harvester, stripping, cleaning, and bagging, 6s.; bags and sewing same, 4s. 6d.; wheat-carting, 1s. 6d.; rates and taxes, 2s.; total, £2 16s. 2d. It will be noted that I have taken the lower value of land—£8 per acre—and have also charged under the average for carting the wheat. On this basis anything above 16bush. would be profit; 20bush., therefore, as an average crop would give a profit of 14s., or 7s. per acre per annum on the land.

Most of you will agree that this is a good average over a period of years for the land I have mentioned. I think it is above the Agricultural College Farm, which may be taken as a fair guide for land at least of the value quoted. and I question if even higher valued land north or south, with the same rainfall, can beat it on purely agricultural lands. My experience is based on 16in. rainfall, and I farm on the third year principle—fallow, wheat, grass. I always apply 1cwt. manure to the acre when cropping, and if anything rather more than less. My holding is 2,800 acres in area and I carry 1,000 sheep all the year, including lambs, also 60 to 70 horses and 15 to 20 head of cattle. In quoting this number of stock it must be added that I get about three months feeding from 200 acres stubble belonging to my son, who adjoins and holds 400 acres, but is working on the alternate system of wheat and fallow. This raises my feeding area slightly, but taking a horse as equal to six sheep and a cow as equal to four, my average comes up to about 1,300 sheep. My system of farming gives me 900 acres fallow, 900 wheat, 1,000 grass.

#### RETURNS FROM THE THREE-YEAR SYSTEM.

Now, the profits being 7s. per acre from wheat-growing on the alternate year system, I wish to show that the returns from the three-year system, with fallow, wheat, and sheep, are equally good, and it is a safer investment.

Take a 600-acre farm as an example, 200 acres in fallow, 200 in wheat, 200 in grass. With the stubble that becomes available this farm would carry 200 ewes with 90 per cent. of lambs. The returns from this farm, on a 20bush. average, would be—wheat, £666; wool, £60; lambs, £135; total, £861. Compare this with the alternate system, of wheat only, on the

same basis, giving £999. There is no allowance on this yield for hay, which would take out at least 15 acres to the hundred, and would represent a difference of quite £50, bringing the difference of returns between the two systems of £135 down to £80. Now, if any farmer can fallow, find the manure, seed, and all the other expenses for 16s. per acre he can teach me something, and I am always out for knowledge on farming methods.

In my comparison of yields I have allowed the same amount for the alternate system as the third year, which, however, is hardly fair to the three-year system for many reasons. One is that the smaller area is more likely to be better worked than the larger. Further, it is very questionable how long the land will stand the alternate system. It will certainly deteriorate, whereas on the third-year system the land will undoubtedly improve, and in years to come will be in better heart than it is at present.

In any kind of farming heavier dressings of manure will have to be given in the future than have been applied in the past to further improve the pasture as well as the crop. My experience proves that the heavier dressings of manure will, on the average with properly worked land, give the greatest profit. There is no extra expense beyond the cost of the manure, which will return a good dividend on the investment.

#### FODDER CROPS.

I am not an advocate of sowing fodder crops for stock to feed off, on the rainfall quoted in my paper, for the reason that one cannot grow fodder crops without rain. When there is plenty of rain there is an abundance of feed. The only exception to this is that where hay-growing is carried on, on the hay stubbles, crops could with advantage be sown for feed. Oats, barley, and rye make a good feeding catch crop, and probably at the end of the season some of it could be saved to reap for grain. In putting this crop in I would only harrow well a couple of times, or preferably cultivate, harrow, and drill in with a light dressing of super. early in March.

It has often occurred to me that on many farms there is too much waste of feed on the one hand, and not enough conserved on the other. Nevertheless, one sees farms that are excellently managed, and which are an example to others.

Hay is undoubtedly the most economical and the most easily conserved of all fodders. It is easily stored, and if properly stacked and protected from the weather is all right for years; in fact, age up to certain limits improves it.

I fail to see that the land is producing all that it might, particularly in our best wheat areas. One may well ask why one farm is returning 20bush. to 25bush. per acre, and over the fence the yield is 15bush. to 20bush.? The land is the same quality; the rainfall is the same; the weather conditions are alike. Is it luck or management? I should say the latter.

If our neighbor can beat us every time let us emulate him : get the points of his success and follow them. Plough when he ploughs, cultivate when he does. If his harrows are out, get yours out, and so on. One essential in wheat-growing is early fallow, and on the plain country plenty of working, particularly with the harrows. This is one of the most important implements on the farm.

#### KIND OF SHEEP TO KEEP.

With respect to the kind of sheep for the farm, I have kept to the Merino ewes, for I think their fleece is more valuable and they are contented sheep. Since breeding crossbred lambs, which I have now done for some years, I first used the Shropshire and Dorset Horn. I have given them up. Firstly, because I found Professor Lowrie was a strong advocate of the Leicester cross ; and secondly, I found a fairly large percentage of ewes of these breeds died at lambing. During the last two years I have used the Border Leicester and the English Leicester, and am very pleased with them. They have a smaller head than the other breeds, and in my experience there has been no more loss from the ewes than there has from the Merinos. The Leicester cross lamb is a fine doer ; it grows quickly, and is ready for the market at four months old. These will dress at 40lbs. to 45lbs. weight at that age. They are also good doers as weaners, and are no trouble to fatten. There is a marvellous difference between them and the Merino if the two are run together. The Leicester ram is like most English breeds—a lazy worker. If a good percentage is required it is best to turn in a few Merino rams to finish off. If kept within good fences to start the Leicester cross lambs are all right. Otherwise fencing is one of their bad points ; but I find all crossbred lambs are alike in that respect. I have so far depended on purchasing a good Merino ewe to breed from. Probably the time is not far distant when we shall have to breed our own. This would make it necessary for us to raise 20 per cent. yearly to keep our flocks up to the desired mark.

I do not recommend farmers on the large holdings I have mentioned to keep cows. They will either be a hindrance to himself, or make slaves of his household. They could be better employed, in my opinion, in working for someone else. Cattle on land that can be cultivated are a hindrance, and where sheep can be kept are very troublesome. Of course, every farmer has to keep two or three cows, but these can be conveniently hand-fed like the working horses. They are then always convenient to the homestead and are very little trouble. With butter, milk, and cream, eggs and bacon, and first class mutton one practically has the fat of the land, and I maintain that a farmer is entitled to live well. He has to work at all times and in all seasons. Further, he produces all the good things, and he should certainly be entitled to what he produces.

On a mixed farm one-tenth of the stock required should be raised annually, so that the working stock are always kept up to the mark. One's own breeding, for many reasons, is preferable to purchased stock.

In conclusion, let me add the thought that a mixed farm on the lines I have advocated is more interesting, as well as more profitable, than the bare fallow and wheat only. It has not the risks, as the stock are always worth something, and they can pull through a dry spell better than the wheat plant.

#### THE DISCUSSION.

Mr. A. A. Jeffries (Mount Bryan) congratulated Mr. McEwin on his able paper. He had, of course, dealt with the subject from the big or gentleman farmer's point of view. Probably most of those present, however, were what were called small farmers, with about 300 to 400 acres. Mr. McEwin had suggested cropping the land every third year, but when a man held only a small area and had to pay, as in his district, £10 per acre for the land, if he only cropped a third each year he would have to make up a lot of money from somewhere to meet his expenses. (Applause.) It seemed to him that the fallow land should be made to produce something. In his district they were fortunately situated, as they could always get at the Burra market a few store sheep. The fattening of store sheep was, he thought, a better proposition than breeding lambs. In buying store sheep they could buy just as many as they could manage to fatten, and they would, he considered, make more by adopting that practice than by carrying sheep all the year round.

Mr. F. Masters (Roberts and Verran) said Mr. McEwin had rather discounted the keeping of dairy stock. He submitted that healthful occupation was not slavery and that it would be to the advantage of the families of farmers if more of them were engaged in the healthful occupation of looking after dairy stock. Then, there was an old saying that it was the pig that paid the "rint," and not many farmers could afford to neglect that animal. There was no more productive animal on a farm than the pig. Mr. McEwin had also said that he did not advocate growing fodder crops, but he (the speaker) maintained that with a 16in. rainfall fodder crops could be grown to advantage.

Mr. F. H. Kelly (Saddleworth) thought that on a small farm poultry, cows, and sheep should all be kept, as the keeping of one worked in with the keeping of the other. He was a strong advocate of growing and conserving fodder, and of hand-feeding sheep when necessary. A good dairy cow would return more per acre than any other animal on the farm.

Mr. E Roberts (Freeling) was quite in accord with Mr. McEwin that if a farmer kept too many cows they were a nuisance. It had been demonstrated conclusively at Roseworthy College that fodder crops could be grown in ordinary seasons. It had been remarked that the breeding of lambs was not as good a proposition as the topping-up of store sheep. He, however, took the opposite view.

Mr. J. C. Hagger (Orroroo) thought the paper was a splendid one, but he did not agree with Mr. McEwin's views as to the keeping of poultry. He had a farm of 1,000 acres, which at the present time would not keep a pack-horse, but he had no difficulty in keeping 1,000 head of poultry. Poultry paid the grocer's bill. Fowls, however, should not be allowed to roam, but should be kept under control. He reckoned that 500 fowls would bring in £2 per week all the year round.

Mr. J. M. Hudd (Hartley) thought Mr. McEwin's paper was a splendid one for a farmer with a large holding. He, however, had only 340 acres on the Burnside Estate, and the settlers there had made money for the first five or six years on the alternate system of one year a wheat crop and the next a spell. That time, had, however, passed, and the wheat yield had fallen considerably. On a small holding like that a man could not crop more than 160 acres, and, taking Mr. McEwin's figures, a profit of 7s. per acre would not pay the rent. He was a great advocate, therefore, of mixed farming. The average man on a small holding could keep a good many irons in the fire and look after them all. If they followed the plan set out by Mr. McEwin, and kept only a few cows, etc., they would not be able to keep their children on the farm. He agreed that it was better to top up store sheep than to breed lambs. The great mistake the majority of farmers made was keeping too many horses. He had 19 head, and this year they were a curse instead of a blessing.

Mr. D. Carman (Pine Forest) said that Mr. McEwin's paper was the outcome of a long experience of farmwork.

Mr. S. Hill (Claypan Bore) said it was true that a good deal of work was attached to keeping cows, but in his district some of the settlers, whose crops were very poor, were, through having four or five cows, in the happy position that the storekeepers were in their debt, instead of the other way about. His experience had led him to strongly advocate keeping sheep on the farm. With cows, a few sheep, and pigs a man could get along. Pigs especially paid well. He did not believe in rearing calves, because a cow could always be bought at less cost than it took to rear one. By keeping cows, etc., a farmer was enabled to provide work for his children, and thus keep his family together.

At this stage the rainfall return for the previous 24 hours was read by the Secretary of the Advisory Board (Mr. G. G. Nicholls), and the announcement of useful falls in many parts of the State was received with applause.

Mr. McEwin, in reply, said one delegate had referred to him as a gentleman farmer. Well, he had been 30 years farming, having started on a little scrub farm, and if any present had had to go through harder times than he had during the first few years he was sorry for them. References had been made to poultry raising, dairy keeping and pig raising. He had had experience of all these, and also of winemaking, and had written according to his experience. His reference to slavery had tickled some of them. Some farmers kept their daughters and sons working hard on their farms, but how much did they pay them? If their daughter was working for someone else she would probably get £1 per week and live like a lady in comparison to what she would at her own home, and their son would easily get £1 5s. per week working for someone else. Farmers should think of these things if they wanted their children to stop home happy and contented. Personally, he had always paid his son wages. He guaranteed that there was no farm equal in size to his own which produced more. To certain farmers cows, pigs, and poultry were good things to keep, but they were not the best for all. Supposing they all raised pigs and poultry, what would be their value? (Voices—"There is the export trade.") The same applied in regard to cattle. The point he wanted to bring out in his paper was that the best was not made of the country similar to that in which his farm was situated. Farmers to-day were on the best wicket of any in South Australia, and no body of men would come through the drought better than they. In his estimate of expenses he allowed for rent and household expenses, and the 7s. per acre was profit. He admitted that in some seasons he had made more than that, and he did not see why his neighbours should not do likewise. One delegate had referred to Roseworthy College as affording an example in growing fodder, but he could not yet see that the growing of fodder crops at the College had been a paying proposition. The paper by Professor Perkins had convinced him that it did not pay to grow fodder crops on fallowed land, because of the adverse effect on the succeeding wheat crop. Of course, where irrigation could be practised the growing of fodder crops was a different proposition.

## IRRIGATION IN SOUTH AUSTRALIA.

Mr. S. McIntosh, Director of Irrigation, read the following paper:—

At the outset let us consider what is meant by the term irrigation. The generally accepted definition of the term irrigation, as a factor in agriculture, is the making up, by artificial means, the deficiency in soil moisture between the total amount of the mean rainfall and the actual crop requirements.

Irrigation as a first factor in agriculture has been practised in arid and semi-arid countries since time immemorial. Egypt, with a rainfall of from 2½ in. to nil, the dry areas of India, Turkestan, China, Japan, and the Valley of the Euphrates are all monuments to the successful continuous practice of irrigation. The records of Egypt clearly indicate that a great nation was dependent upon the waters of the Nile for its existence at least 4,000 years B.C., and to-day on less than 12,000 square miles there is a population of approximately 10,000,000. Parts of India likewise depend almost solely on its irrigation supplies to avert periodical famine. India proper is about half the size of Australia, yet it carries a population of 300,000,000. China proper is about one half the area of our continent, and has about 400,000,000 souls. Japan, about one-eighteenth of the area of this continent, holds over 46 millions, while Java, one of the most intensely irrigated islands of the East, only about one-sixtieth of the extent of the Commonwealth, contains over 30 million inhabitants. In Australia the population is less than five millions. In view of the fact therefore that we possess a very large area of country of an arid and semi-arid nature, it behoves us to make the best use of the water that is available.

## ON THE MURRAY IN SOUTH AUSTRALIA.

Along the Valley of the Murray an extent of over 25,000 acres is irrigated, or partially irrigated. There is also an area of considerably over half a million acres which is capable of being successfully irrigated. This includes the areas in course of, or capable of reclamation, throughout the entire length of the Valley of the Murray in South Australia. On the Government irrigation areas there are now 221 lessees, occupying 4,744 acres of irrigable land, and in addition there are 1,266 acres awaiting allotment. These blocks have already been over applied for, which clearly indicates that the public of South Australia is awakening to the value of water as a factor in procuring successful results in agriculture and horticulture.

A further 37,690 acres are being prepared for irrigation by the construction of channels, and the erection of suitable pumping plants. Of this area it is anticipated that 1,133 acres will be allotted before the end of this year. A further 3,000 acres of similar country will be available for allotment within the next two years.

It is estimated that when the scheme is completed at Cobdogla there will be 40,000 acres under irrigation, together with a very considerable area of high land suitable for farming and grazing.

The water rates per acre throughout the irrigation areas which are under the Government control are at present fixed at 30s. During the first year of occupation the settler pays 7s. 6d. or  $\frac{1}{4}$ ; for the second year 15s., and for the third, 22s. 6d. From the fourth year onward the full amount of 30s. is paid. The rate is based on the actual cost of raising the water plus interest, depreciation, and a sinking fund. For this amount the settler is entitled to 24 acre inches, or the equivalent of 24in. of rainfall. This, in addition to the average rainfall, which is approximately 10in. per annum, will provide ample for general requirements. Further water may be furnished at excess rates, while on the other hand a concession or rebate is proposed to such persons as actually use not more than 18 acre inches.

#### POSSIBILITIES UNDER IRRIGATION.

We will turn from the consideration of the Murray works to deal with the possibilities of production, under our climatic conditions generally, by means of irrigation. This unfavorable season brings home the great value of water supplies as a national asset in times of drought. Two acre feet of water (the equivalent of 24in. of rainfall) contain 202 tons or 271,476galls. Applied systematically to a suitable soil possessing a slow but efficient drainage this quantity may be made to produce a return in lucerne of 40 tons of green fodder, or 10 tons of dry hay. In a year like the present this can be valued at £3 to £4 per ton; a total value of £30 per acre. On some of the reclaimed swamp lands crops of from 12 tons to 15 tons of hay are not uncommon. From these areas, amongst other returns, we have had up to 30 tons of onions and 20 tons of potatoes per acre, while from two to three milch cows and 30 sheep to the acre for nine months in the year are comparatively common results. It is estimated that it takes approximately 300lbs. to 350lbs., or even more, of water applied to make one pound of dry matter. The volume of water referred to above, applied to cereals will ensure a hay return of oats or wheat of from 3 tons to

4 tons per acre, and this can be followed by a summer crop of sorghum or maize—yielding from 30 tons to 40 tons of green fodder.

With such crops as these it follows that there is an exceptional drain on the natural plant food constituents of the soil. Therefore to ensure permanent success liberal dressings of suitable manure must be applied. This will be dealt with later.

#### QUALITY OF WATER AND NATURE OF SOIL.

For the man who would irrigate, the first consideration is the quality of the water, i.e., its suitability to assist in the successful growth of economic plant life. This is often a perplexing problem, as so much depends on the nature and amount of alkali, or salts in the water, and the general character of the soil to which such water may be applied. It is a generally accepted rule that the water should not contain more than 70grs. of carbonates (other than calcium) and chlorides per gallon, although in Egypt, a mineral content of over 200grs. per gallon is recorded as having been used. Up to the present the water containing the greatest percentage of salts of which we have any record as being used successfully in this State showed from 173grs. to 183grs. of total solids per gallon, or from 106grs. to 145grs. of common salt per gallon. This water has been used for about nine years on a soil consisting of a dark loam over a limestone subsoil, which ensures good drainage. Nevertheless on many soils on which irrigation has been attempted, even one-half of the above percentages would have proved fatal to all plant life. Those who desire to use water for irrigation purposes, the quality of which is not already known, should first of all have an analysis made to learn whether it is suitable. I understand that the Department of Agriculture will, at the discretion of the Director, have such analyses made free of cost for landholders who make application. Wherever the water contains over 50grs. of injurious or excess alkali to the gallon, the greatest care should be exercised in the selection of the land to be irrigated. In the first place it must not contain more than one-fifth of 1 per cent. of sodium chloride or common salt, the generally accepted rule being that any soil containing more than one-fourth of 1 per cent. is unfit for most culture plants; secondly, the soil must have a thoroughly effective drainage system. A successful irrigation plot should possess a good sandy loam from 6in. to 4ft. or 5ft. in depth over a fairly retentive marl-clay subsoil, with a slow but perfect drainage. Soils to be avoided may be described as follows:—(1) Pure sand or gravel to any great depth; (2) limestone rubble, boulders, or rock on the surface, and to

a depth of several feet; (3) close and heavy clay; or closed in flats of a clayey nature without a natural drainage or get-away for the excess water.

#### SOURCES OF WATER SUPPLY AND MEANS OF CONVEYANCE.

Those who are contemplating constructing dams or weirs for impounding flood waters for irrigation purposes I strongly advise to first consult some competent authority, as an improperly constructed erection is a menace to all concerned.

From national or State supplies other than the Murray River, the water is almost invariably carried on to the plots by means of pipes. From springs, artesian overflows, and wells, under certain conditions, the necessary supply can be made available through pipes or open channels. In America, where wells containing good supplies are sunk on convenient slopes channels are driven to enable the water to flow from the bottom of the well on to the soil surface. For example, a well 30ft. deep would contain drives radiating from the centre to ensure a maximum supply. Supposing the slope to have a fall of one foot to the chain the actual water level on the soil surface would be at a point 30 chains from the site of the well, but to guarantee an adequate flow of the stream the channel or pipe line would be brought to the surface at say 40 chains from the source, whence it would be taken by gravitation in the usual manner.

On the reclaimed areas of the Murray and similarly constituted lands the water is supplied through sluices placed in the banks or levees.

The various methods of irrigating lucerne and fodders are as follows:—

- (1) General flooding from an elevated flume through distributory pipes.
- (2) Flooding from an earthen, concrete, or other head ditch on to rectangular or irregular plots and open borders.
- (3) Furrow irrigation.—This is a system usually practised in orchards.
- (4) Contour ditches.
- (5) Sprinklers.
- (6) Underground pipes.—This is certainly the most up-to-date method of applying water, as there is a minimum of evaporation, and the maintenance of the channels is likewise reduced to a minimum. The best pipes used are made of compressed concrete.

## FARMERS' LUCERNE PLOTS.

Probably many farmers will have limited supplies of water suitable for growing a relatively small plot of lucerne—to keep their horses healthy, and to add cream to the milk of the domestic cow. In such cases I would recommend the erection of a tank as already suggested, at a height of approximately 12ft. to 20ft. from the ground, if sprinklers are to be used. Sprinklers are of little use on extended areas, although they are very suitable for garden plots and small lucerne patches which can be watered during the early morning, in the evening, or at night.

In laying out this system, everything depends upon the water pressure; where it is low, sprinkling is not a success. First ascertain the water pressure, then lay out supply pipes at regular intervals accordingly, either with fixed sprinklers to command the full area, or stand and tap to which a hose can be affixed and an effective distributor attached. These are set upon a given area, and as soon as it is sufficiently saturated they are removed and set up again, care being exercised to see that the outside spray meets, and thus waters the whole.

The fixed system of sprinkler is not recommended, as with a falling pressure it is ineffective, added to which the expense of installation is prohibitory to anyone but the comparative capitalist.

Amongst other objections to sprinkling on a large area are the following:—(1) The cost of installation of the system; (2) damage done to tender plant growth by scalding when the water is applied by this process on particularly hot, calm days; (3) loss of water and damage to tender growth when being applied during a spell of hot winds; (4) damage to growing crops in moving the sprinklers and hose; (5) the impossibility of satisfactorily watering tall maize or sorghum crops; (6) danger of watered circuits not meeting, and portion of the crop being left unirrigated.

Some valuable lessons may be learned at Roseworthy College on the subject of sprinklers. Where the plot to be irrigated is less than half an acre in extent, I have no hesitation in recommending two or three standpipes, and a 3-ply hose, with good sprinklers attached.

Land intended for lucerne must possess a good drainage to secure successful results. It does not particularly matter as to the quality of the soil, so long as it does not contain too high a percentage of clay or alkali, but a fairly deep loam of sandy rather than a clayey nature is best. The area should be fallowed at least three months before sowing, the weeds eradicated, and the soil well worked up with a scarifier, disc, or Acme harrow and pulveriser and rolled

when ready for the seed. With a properly-prepared seed bed, from 10lbs. to 15lbs. of good seed is sufficient to ensure a satisfactory stand. The soil should, if possible, contain a sufficiency of moisture to germinate and carry the plant into its fourth leaf, or, better still, until it is 4in. or 6in. in height. Harrow lightly or brush the seed in, and again roll the land, with the object of excluding as much air as possible and securing a firm seed bed.

I prefer to broadcast the seed, as I have found that the moisture dries out more rapidly from the drilled plots than from the broadcasted after the plant is cut, while if grazed between seasons the sheep eat off the crowns of the plants in the drills to a greater extent than where the seed has been broadcasted.

#### FRUIT TREES AND VINES ON THE FARM.

To irrigate fruit trees or vines a plough furrow should be run out on a down grade a foot or more from the stem of the tree on the low side. The water should be conducted through a small pipe, or cut from the head ditch (which is invariably placed on the high side of the orchard or vineyard) into the furrows, and allowed to run slowly down the rows until the intervening space shows signs that it is properly soaked. Care should be taken not to over-irrigate. Thorough cultivation should follow as soon as possible after watering. Cultivation is as essential with irrigation as it is with dry farming.

#### WATER VALUES.

It is a general experience throughout the world that cheap water usually results in slovenly and wasteful methods of application, and the higher the cost of the supply the more successful and up-to-date the irrigators are. After nearly a quarter of a century of practical experience of irrigation I am satisfied that the practical man whose soil is suitable, can afford to pay £1 or more per acre-foot for his water supply, and can make a thorough success of his undertaking.

As an illustration of what can be paid for water for irrigation purposes, it may be stated that on a Chaffey Settlement in Whittier, California, from £3 2s. 6d. to £6 5s. per acre per annum is paid. To secure this water the settler must in addition, purchase a water right at a cost of £70 per miner's inch, equal to £15 11s. 8d. per acre.

The bare land within the irrigation area commands from £100 per acre upwards. Payment for water rights extends over 10 years. Terms, however, may be secured for the purchase of the land. Matured and first-class orange orchards realise from £500 up to £1,000 per acre in this section. From the best of these lands the

crops net up to £170 per acre. On the Murray settlements we possess citrus lands of equal value, as far as crop returns are concerned.

All the water required is pumped to a height of 103ft., from wells of considerable depths; it then gravitates through pipes for a distance of 14 miles, when it is again pumped up to two higher levels.

When in the Roosevelt irrigation area I noticed that quite a number of the lucerne paddocks were veritable swamps. Crops were thin and dwarfed with rough grasses showing up prominently. In some of them stock were grazing while the irrigation was proceeding. The engineer stated that water was demanded every eight days for lucerne by a majority of the settlers on this section of the scheme—others wanted it almost continuously. None of these people were more than eking out an existence. Yet they did not pay more than 10s. per annum for all the water they use.

Some distance down the valley beyond the irrigation area there is situated a ranch belonging to a Dr. Chandler. Wells have been sunk across the line of drainage from the "water-wasters" above; these wells are fitted with 8-in. or 10-in. centrifugal pumps and electric motors; water is raised from a depth of 35ft. to irrigate over 2,000 acres of lucerne, the finest stand of this valuable fodder I have ever seen. The crop is cut from six to seven times annually, hay yields run from 7 tons to 14 tons per acre, the average being about 10 tons. This is sold on the farm at from £2 2s. 6d. per ton upwards. The hay crop is cut, raked, and stacked with the latest hay-harvesting machinery.

#### SELECTION OF PLANT.

Assuming that water and soil are both satisfactory, we will now consider the selection of the plant, providing a pumping outfit is required. In this we must be guided by the quantity of water and area of land available. With plots of an acre or less in extent, provided that the site is exposed and prevailing winds may be depended upon to supply the necessary driving power, a strong, modern wind-mill and pump, both of approved design, with a storage reservoir to hold from a thousand gallons of water upwards, should meet all requirements. If the prospective irrigator possesses a portable oil engine or motor, with the addition of a small centrifugal pump, a safe auxiliary is provided to maintain the necessary water supply in the event of a long spell of calm or hot weather. Wherever practicable, an up-to-date centrifugal pump should be used. For areas of an acre up to 100 acres the latest improved oil engine or motor (paying due

regard to economy in consumption of fuel) is recommended. From 100 acres onward, where the firewood supply is plentiful and cheap, a good, reliable, and economic steam plant can be safely depended upon to give satisfaction, but where the natural fuel supply is at all doubtful, the latest type of wood or charcoal gas producer-plant will maintain first place until it is displaced by a new and more economic power.

As regards the bigger plants referred to, the records of the Irrigation Department giving the consumption for the respective sources of power will be of interest. They are as follows:—Ordinary gas suction producer, 1lb. charcoal, equals 4lbs. wood, per h.p. per hour; super-heated steam, 3lbs. wood per h.p. per hour; Cambridge wood gas, 2lbs. wood per h.p. per hour. In respect to the last it is anticipated that a further economy will be effected.

The total amount of moisture required to secure the best results, with the aid of careful cultivation and judicious application of the artificial supply on an average soil, is estimated at about 30in. Assuming 12in. to be the mean annual precipitation, this leaves a balance of 18in. to be provided, to which should be added another 4in. (a low estimate on large areas) for evaporation and seepage losses when the water is delivered through the medium of open flumes and channels. The necessary pumping or other supply plant must, therefore, be capable of furnishing a total of 22 acre-inches, or approximately 500,000galls. per acre per annum distributed over the six or seven months in the irrigating period.

Thousands of pounds have been squandered by beginners in the purchase of unsuitable machinery, attempts to irrigate with limited or bad water supplies, the selection of unnatural irrigation sites, and in various other ways. Surely we should benefit from such examples instead of blindly repeating them. Nevertheless, the average beginner thinks that he knows all there is to learn in the business, but in nine cases out of ten finally arrives at the conclusion that practical guidance would have saved him much labor, time, and cash.

#### MANURES TO APPLY.

Use every available load of stable or sheep manure and any humus available on the irrigation plots. Where these are not to be obtained, dress the soil with from 2cwts. to half a ton of bone super, or other phosphatic manures. Apply all such fertilisers immediately before irrigation to ensure their being worked or soaked into the soil, and thus made available as plant food.

Where the soil surface is inclined to run together, or form a hard crust, air-slaked lime or gypsum should be spread over the plot. At Renmark, Lyrup, and elsewhere along the river dressings of five tons to seven tons of gypsum per acre are not uncommon.

#### SUMMARY.

In concluding this paper the following suggestions are offered:— If you seriously contemplate going in for irrigation, seek the advice of the successful agricultural and horticultural irrigationist, or engineer with some local experience. Close your ears to purely theoretical irrigationists who would attempt to persuade you that irrigation under any conditions must prove an unqualified success. Should you be so situated that you cannot secure the desired information in the matter, be guided as follows:—

1. Be sure the quality of the water is suitable (this can be ascertained by analysis), and that the supply is sufficient for your anticipated requirements.

2. Satisfy yourself as to the suitability of the cultivation site for economical irrigation.

3. When ordering a pumping plant insist upon at least 25 per cent. more power than is actually required. Secure a written guarantee and insist upon a practical test from the firm supplying the plant, so that in the event of its not meeting your specified requirements you incur no loss or expense. The aim of the irrigator must be to see that an efficient supply of fresh water is applied to suitable soil, with the greatest degree of economy, through the medium of the simplest machinery.

4. Erect the plant as near the water supply as is consistent with safety and economy. Be sure your foundations are solid and permanent. If engine power is required erect a shed which is sand proof, over the whole plant.

5. Remember that the maximum suction in practical work is from 20ft. to 24ft.—therefore keep the pump as close to the water level as practicable. If possible, suction pumps should be straight, and the lower end should not be less than 2ft. below the lowest water surface level. The following table gives the correct ratio between pump openings and suction and discharge pipes:—

| Diam. of Pump<br>Opening. |       | Diam. Suction and<br>Discharge Pipes. |
|---------------------------|-------|---------------------------------------|
| In.                       |       | In.                                   |
| 3                         | ..... | 5                                     |
| 4                         | ..... | 6                                     |
| 5                         | ..... | 8                                     |
| 6                         | ..... | 10                                    |
| 8                         | ..... | 12                                    |
| 10                        | ..... | 15                                    |

Suction pipes must be kept free of all air leaks, the flame of a lighted candle, if held near the joint will disclose the smallest leak. If a valve is necessary, make sure its area is sufficient and equal to the diameter of the suction pipe. Use either a head valve, in which case an air ejector is necessary to create the necessary vacuum in the pump chamber and the suction pipes, or a foot valve placed in the pipe as close to the bed of the pump as is convenient, where, in the event of it going wrong, it can be examined without the necessity of hauling up the full length of suction pipe or the employment of a diver.

6. Discard the usual strainer. If one is necessary, construct it of galvanized wire or bars, with at least four times the cubic capacity of the original—as offered or supplied by the makers.

7. Do not use pipes with a rough inside face. Never use a short right angle bend. Insist upon long bends or sweeps, if such are necessary.

8. Do not pump the water higher than the point at which the bulk of it is actually required. If the lift and area warrant it, provide offtakes and stop-cocks at the various levels.

9. Keep all flumes and channels clean and in good repair, engine and pump glands well packed, and bearings properly lubricated with the best brand of lubricant.

10. Supply your crops with a drink at the right time, i.e., when they require it. Do not wait until they are languishing or dead before you commence irrigating.

11. From 10 acres to 25 acres of irrigated land, under intense culture, is quite as much as the average family can profitably occupy and work.

12. Land should be maintained in good heart by judicious fertilizing from the start, and if of a poor quality a high standard of fertility should be attained before the crops commence to draw upon the supplies of the necessary and available plant food.

13. There is danger through over-irrigating of washing the plant food constituents out of the soil. To maintain a maximum condition of soil fertility cultivation and the use of a minimum water supply, commensurate with actual crop requirements, is essential.

14. Unless the natural drainage is good an efficient drainage system must be provided.

15. Only the best marketable fruits, vines, fodder, or root crops should be planted, and these only on the locations proved to be suitable for the same.

16. So arrange everything that you can run the plant and irrigate at night during excessively hot weather.

17. The successful irrigator must of necessity be a thinker, a close and careful observer, and must follow commonsense practices throughout.

#### BIBLIOGRAPHY.

The following publications will be found of value in connection with this subject:—

#### A CANADIAN VISITOR.

The chairman announced that among the visitors present was Professor Edward E. Prince, of Ottawa, Commissioner of Fisheries for the Dominion of Canada. On their behalf, he heartily welcomed Professor Prince, and asked him to address the Congress.

Professor Prince acknowledged the chairman's kindly greeting. It was a pleasure for him to have the opportunity of being present at that congress of agriculturists, as it must be recognised that the agriculture of a country was its greatest asset. The Government could not do too much, nor could the public, to encourage and help the farmer to make the best of what divine Providence had placed in their hands. (Applause.) In coming through South Australia he had been impressed, perhaps more than in any other part of Australia, with the beauty of some of the landscapes, and yet was told

that he was seeing it under the most disadvantageous circumstances. (A voice—"We have never before had a season like it.") It was most extraordinary, and he thought such a country had a very great future. They boasted in Canada of what they were going to do some day, when they had 100 million people. What he would like to see would be a great increase in the population of Australia. (Applause.)

In recognition of the rain the Doxology was sung, and Congress then adjourned till 7.30 p.m.

### **EVENING SESSION.**

Mr. G. R. Laffer, M.P. (Chairman Advisory Board) presided over a large attendance of delegates and visitors.

### **REPLIES TO QUESTIONS.**

Replying to questions, Mr. McIntosh said in regard to irrigating lucerne, it was better to give one watering of, say, 3in., allowing for evaporation, than two waterings of 1½in. each. The best results on the river blocks were obtained by watering a week before cutting, and about a week after. Assuming that the water from a bore was sufficiently free from salt, there was no objection to watering by sprinklers. As a precautionary measure it was advisable to pump the water into a storage tank, and allow it to stop there for, say, 48 hours before using. In the modern centrifugal pump, which he advocated, there was nothing to get out of order; but that was not the case with the force pump. Those who intended planting lucerne should see that the seed was not more than two years old. The depth to which the water should be kept on reclaimed lands depended entirely on what crop was to be grown. So far as lucerne was concerned, on the high lands the water must be down at least 6ft. He had had five cuts from Berseem sown in March. In places where a good stand of lucerne could be established, but where it was not possible to irrigate, he advised trying Turkestan.

### **FREE PARLIAMENT.**

The Director of Agriculture, in reply to questions, said that the average bushel weight of Cape barley was 50lbs., and of malted barley 56lbs. Weight for weight per bushel, therefore, malted barley was of better feeding value than Cape barley. Whether it would pay a farmer to undertake experimental work, such as wheat

selection, depended on the temperament of the person concerned. If properly carried out, unquestionably it would pay. It was, however, no use a man undertaking anything like that unless he had a liking for the work, and was prepared to take the trouble necessary.

#### NORTHERN BRANCHES CONFERENCE.

Mr. F. Coleman (Vice-Chairman Advisory Board) said that at the last conference at Gladstone of the Northern Branches of the Agricultural Bureau the opinion was expressed that the district represented was too large, and that some of the branches were too far removed to allow of their representatives attending. He moved—"That it be a recommendation to the Advisory Board of Agriculture to divide the northern district into two districts, and to arrange that a separate conference in each of the proposed districts be held annually." If the resolution were given effect to, the arrangement that the conference of the northern branches be held at Gladstone would still hold good.

Mr. F. H. Kelly (Gladstone) seconded the motion, which was declared carried unanimously.

#### MAYOR'S PATRIOTIC FUND.

On the motion of Mr. F. MacMillan (Bookpurnong East), seconded by Mr. J. Parkes (Waikerie), it was resolved that a collection for the Mayor's Patriotic Fund be made. The collection amounted to £9 8s. 11d.

#### SOIL WATER IN RELATION TO PLANT GROWTH.

Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S. (Principal Roseworthy Agricultural College), read the following paper:—

The presence of an adequate amount of moisture in a soil is essential to its fertility. All soils in a natural state contain some water, even in seasons of drought, but it may be so tightly held by the soil grains that it is not available to the plant roots. As a general principle it may be stated that the capacity of a soil to furnish an abundant supply of water is one of the most important factors determining its fertility. In some humid regions the soil waters accumulate to excess, and the important role played by moisture in plant nutrition and some metabolism is masked by the inhibiting action of a persistent overplus. It rarely happens, however, even in heavy rainfall districts, that a sufficient supply of moisture is provided *during every phase of the growing period of a crop*. In arid regions, or in droughty seasons, within the boundaries of fair rainfall, the vast importance of soil moisture is obviously paramount. No finer illustration can be cited in this connection

than the transformations effected along the banks of the Murray River by means of irrigation. In South Australia we have districts that suffer periodically from an insufficient supply of soil moisture, and also others that are just as frequently laid waste by excessive water. In a general study of this question considerable emphasis would naturally be given to the conservation of moisture in dry areas, but in this paper I propose to consider chiefly those aspects of the subject that assume importance in notoriously wet districts. The Government has been the means of throwing open to farmers land that in the past has been neglected by cultivators on account of the risk of destructive inundations in the winter and spring months. In the near future a very much larger area of similar country will in all probability be brought under closer settlement. There is, therefore, ample justification for inviting Congress to consider the problems that confront those who elect to settle on this class of country.

The difficulties that beset the men in the drier areas have been met, and in a large measure overcome by an intelligent study of the soil in its relation to moisture and plant nutrition, and those who are grappling with the cropping problems of our wet districts cannot do better than follow this example. In order to be able to make logical deductions from observed phenomena it is essential that the man on the land should be conversant with the fundamental laws affecting the factors of fertility in the district in which he is working. In some of the wetter districts farmers are faced with two distinct problems. In the raising of autumn or winter sown crops they are concerned with surplus water and the means of excluding or discharging it from their fields. Whereas, in the case of spring and summer sowings, they are often puzzled to know how to maintain the soil in a sufficiently moist state. These two problems are really very closely connected, and it will be shown later that the remedial measures adopted towards the solution of the one will materially assist in the elimination of the difficulties involved in the other.

At the outset it may be stated that green plants will absorb a certain amount of dew and rain directly through the pores of the leaves and the stems when they are in a flaccid or wilted condition, but that, apart from this particular case, the whole of the plant's water supply is absorbed from the soil through the roots.

The amount of water required by crops for their full development is very considerable. This is not surprising when we remember that from 75 to over 90 per cent. of our farm crops consist of water. More important than this, however, is the amount of water transpired, *i.e.*, evaporated from the plant during the growing period. A number of investigations have been made to ascertain the amount of water used by crops in the process of building up their tissues, and very variable figures have been obtained. The following table sets out the results secured by four different experimenters.

TABLE I.—*Water Evaporated by Growing Plants for one part of Dry Matter Produced.*

| Lawes and Gilbert— |     | King—            |     |
|--------------------|-----|------------------|-----|
| Beans .....        | 214 | Maize .....      | 272 |
| Wheat .....        | 225 | Barley .....     | 393 |
| Peas .....         | 235 | Potatoes .....   | 423 |
| Red Clover .....   | 249 | Red Clover ..... | 453 |
| Barley .....       | 262 | Peas .....       | 477 |
|                    |     | Oats .....       | 557 |
| Hellriegel—        |     | Wollny—          |     |
| Beans .....        | 263 | Maize .....      | 233 |
| Peas .....         | 292 | Millet .....     | 416 |
| Barley .....       | 310 | Peas .....       | 447 |
| Red Clover .....   | 330 | Sunflower .....  | 490 |
| Wheat .....        | 359 | Buckwheat .....  | 646 |
| Buckwheat .....    | 371 | Oats .....       | 665 |
| Lupin .....        | 373 | Barley .....     | 774 |
| Rye .....          | 377 | Mustard .....    | 843 |
| Oats .....         | 402 | Rape .....       | 912 |

If we take the figures given for peas we observe that the number of pounds of water extracted from the soil per pound of dry matter produced varies within very wide limits, namely, from 235lbs. to 477lbs. Obviously, therefore, it is difficult to trace any definite relationship between the amount of water transpired and the growth of the crop. More recent experiments have shown that the ratio will vary according to the conditions. With a rising temperature, and an increased water supply a larger amount of water per pound of dry matter will be evaporated, and when the available plant food is abundant the water requirements of the crop will be lower. The pores of the leaves are so constructed that a plentiful supply of water in the tissues of the plant causes them to open to their fullest extent, and so permit free evaporation. On the other hand, when soil water is insufficient to maintain the plant in a strong growing turgid state the leaf openings or stomata tend to close up. This is clearly an effort on nature's part to enable plants to attain their full development under varying conditions of growth. It is none the less true, however, that although plants may reach maturity on a limited supply of moisture, maximum development can only be attained when the supply of soil water is lavish. Before leaving this part of the subject there are two interesting experiments deserving of attention. They were both designed to throw light on the effects of a varying water supply on plants grown under different manurial systems. The first was carried out on oats with the following results :—

TABLE II.—*Effect of varying Water Supply and Food Supply on the Water Requirements of Oats.*

|                       | Water required per gram of Dry Matter, |             |                   |
|-----------------------|----------------------------------------|-------------|-------------------|
|                       | Soil Moist.                            | Soil Moist. | Soil still Moist. |
| No Manure .....       | 259.9                                  | 312.9       | 307.1             |
| Complete Manure ..... | 225.1                                  | 236.8       | 231.6             |

The results go to show that plants do better in dry seasons when the food supply is plentiful, or, as we say, when the land is in good heart. The figures also indicate that in droughty years when the water requirements are in excess of rainfall, portion of the manure will be lost to the crop.

The second experiment was also on oats, and the results obtained from it bear out the conclusion that the water supply exerts an important influence on the effectiveness of fertilisers. The details of the work are shown below :—

TABLE III.—*Influence of Water Supply on the effectiveness of Phosphates.*

|                        | Dry Weight of Oat Crop in Grams. |                      |                                             |                                                                     | Increased Crop for—                      |                                           |
|------------------------|----------------------------------|----------------------|---------------------------------------------|---------------------------------------------------------------------|------------------------------------------|-------------------------------------------|
|                        | No<br>Manure.                    | Potash,<br>Nitrogen. | Potash,<br>Nitrogen,<br>Phosphoric<br>Acid. | Potash,<br>Nitrogen,<br>Phosphoric<br>Acid<br>(double<br>quantity). | First<br>Addition<br>Phosphoric<br>Acid. | Second<br>Addition<br>Phosphoric<br>Acid. |
| Moist Soil .....       | 41.5                             | 38.5                 | 68.5                                        | 79.2                                                                | 30.0                                     | 10.7                                      |
| Moister Soil.....      | 47.2                             | 40.0                 | 93.4                                        | 108.0                                                               | 53.4                                     | 14.6                                      |
| Still Moister Soil ... | 68.5                             | 63.5                 | 119.5                                       | 127.5                                                               | 56.0                                     | 8.0                                       |

These figures reveal an increase for the first addition of phosphoric acid in the least moist soil, and also a slight increase with the second addition. In the "moister" soil a much larger increase followed the first addition, and in the "still moister" soil the increase in yield is still higher. The difference, however, was so small that it would seem that any further increase in the amount of moisture would be disadvantageous. The practical value of these experiments lies in the definite knowledge acquired that what is the correct amount of manure to apply in one season may fall short of or exceed the optimum quantity under a different total or a differently distributed rainfall. Dr. Russell expresses the same fact when he states that "a given increase in the food supply may produce no increased growth, small increase, or large increase, according to the extent of the water supply."

Plants require much more liberal supplies of water during the period of active growth than in the germinating or ripening stages. After growth has ceased, and the energies of the plant are directed to the transportation of material from its vegetative tissues to the grain, the presence of abundant moisture commonly results in diminution of the yield. In wet soils the foliage is profuse, the growing period extended, and the maturing process unduly protracted.

The soil moisture is derived mainly from the rainfall; small quantities are also deposited in the form of dew and condensed water that has emanated from the subsoil. It is not always the rain that falls on a field that contributes even the greater part of the soil moisture. The subsoil may be receiving subterranean supplies from distant sources, or surface springs may furnish a continuous and copious flow. Water may be present in a soil in two or three

different forms. If we take a soil that has been wholly deprived of its moisture and add a very small quantity of water to it, the soil will not be made perceptibly moist thereby. This is because the water, which is termed *hygroscopic moisture*, has entered into chemical union with some of the soil ingredients. This water is not available to plants, and can only be driven out of the soil completely by heating up to a high temperature. Although of no direct use to plant life it is possible that hygroscopic water aids the solution of natural and applied plant food. This action, however, would of necessity be very slow if no other form of moisture were present.

If we add a little more water to the originally dry sample we will notice that the soil moistens, and that the additional supply of water is held by the soil particles with such force that it cannot drain away or percolate. This is the useful form of soil moisture on which plants and soil organisms depend. It is known as *capillary moisture*, and adheres to the surfaces of soil granules and plant roots by surface tension. It is due to the force of surface attraction that capillary water is enabled to move freely in all directions through the soil. Since it constitutes the solvent and vehicle of the elements of plant nutriment in the soil it is necessary for it to be in a constant state of steady motion.

To return once more to our dry soil. The addition of yet another supply of water will bring about a saturated condition. The water-retaining powers of the soil are now no longer able to hold the additional supplies against the force of gravity, and the water simply percolates through, in a well-drained soil, or else remains to clog the pores and water-log the land. This excess, or free water, is known as *hydrostatic or gravitational moisture*. When it finds its way into drains it comes to be known as *drainage water*. This surface water is harmful to plant life in several ways, and land saturated with it will never produce satisfactory crops.

#### GRAVITATIONAL WATER.

In the drier areas, and in the successful culture of summer crops in relatively moist districts, the main objective is the retention of capillary water, but farmers in the humid districts are chiefly concerned with gravitational water.

The point of distinction between capillary and drainage waters will vary with the absorptive and retentive powers of the soil for moisture. These properties again will depend upon the porosity of the soil and the presence of certain colloid bodies of which humus is the most important. The total amount of water required to saturate different soils under field conditions varies from 30 per cent. to 50 per cent. of the whole volume, being greatest in peats and fine-grained clays, and least in the coarse sands. When a soil is fully charged with water, however, it is devoid of air, and, therefore, cannot support vegetable life. The question then arises as to what is the optimum amount of moisture that a soil should contain to fit it for the production of a maximum amount of healthy plant growth. Another investigator working with barley has shown

that the yield rises up to a certain point with increased supplies of water, and then falls again with further increments. Experiments quoted by Warrington indicate that the largest crops will usually be obtained when the proportion of water present is about one-half the amount required to saturate the soil. The injurious effect of an over-supply of soil water is due to the exclusion of oxygen from the living roots, and the production of poisonous bacterial products in a de-oxygenated atmosphere.

In nature most soils are drained to some extent, and complete saturation only occurs where the water level rises almost to the surface or above it. It is possible for the surface of the ground water to be so near the top layer of soil that the land, though apparently normal in water content, is unsuited for cropping. The capacity of different soils to yield up their moisture to plants has an important bearing upon this subject. The coarse-grained soils, i.e., those with the least internal surface and the lowest water-holding capacity yield up their moisture freely. King carried out an interesting piece of work relative to this point on four different types of soil. He found the water content of these soils, when they had just reached the stage of dryness that prevented them from supporting further plant growth. In the appended tabular statement of his results figures indicating the minimum and maximum limits of soil moisture for luxuriant growth on these soil types are included :—

TABLE IV.—*Soil Moisture Relations when Growth is Brought to a Standstill.*

|                  | Clover.   | Maize.    | Lower Limit<br>of Soil<br>Moisture. | Upper Limit<br>of Soil<br>Moisture. |
|------------------|-----------|-----------|-------------------------------------|-------------------------------------|
|                  | Per cent. | Per cent. | Per cent.                           | Per cent.                           |
| Clay loam .....  | 8.43      | 7.30      | 17.01                               | 25.77                               |
| Red clay .....   | 12.84     | 11.79     | 19.86                               | 24.30                               |
| Sandy clay ..... | 13.52     | 10.84     | 18.56                               | 24.03                               |
| Sand .....       | 9.53      | 4.17      | 15.90                               | 22.29                               |

#### SOIL DRAINAGE.

An important deduction from this table is that different types of soil may be equally dry as far as crops are concerned when they contain widely differing amounts of moisture, for instance, sand continued to yield moisture to maize until its water content was reduced to 4.17 per cent., whereas the red clay ceased to supply the same crop when it contained nearly three times as much water. This means that it is possible for a retentive soil such as clay to have a higher water content than a porous soil such as sandy loam, and yet the latter may furnish a greater amount of water available for absorption by plant roots. This serves to explain why sandy soils produce relatively better growth in relatively dry seasons. Open porous soils do best when the rainfall is made up of a series of light showers that continue to fall periodically through the greater part of the growing period. Under these circumstances crops growing on heavy land make slower progress in the early part of the year, and

are more liable to suffer from hot winds later on, than those on the lighter soils. In wet districts sandy land does not show to such advantage, as the free percolation of large quantities of water leaches out much of the soluble plant food. Nevertheless, the free passage of excess water is essential to the fertility of all agricultural soils. Fortunately, over most of our arable lands the surplus is removed naturally by seepage or surface flow. The most fertile soils we possess are those naturally or artificially drained areas situated within the boundaries of abundant rainfall. It remains, therefore, for those entrusted with the development of farm holdings in the humid areas of the State, and on the irrigation settlements to focus their attention on the subject of soil drainage. The benefits that accrue from drainage do not become immediately apparent, and a year or two may elapse before the good effects are revealed, but the accumulation of gravitational water is so obvious a phenomenon in many districts that the advisability or otherwise of providing artificial drainage cannot be deemed an arguable subject. A review of the chief services rendered by field drains may help to disperse such misgivings as are still lingering in the minds of many occupying drainable areas. Briefly these are as follows :—

1. In all soils the process of weathering leads to the formation of soluble matters, and when the soil moisture is surcharged with these substances, whether they be plant foods or not, the plants supplied by it succumb. Under irrigation in dry districts the same trouble occurs, even when the water used is practically pure, and a sufficient number of soakings must be given to maintain the soil water in a proper state of dilution. The first purpose of drainage, then, is to control the concentration of the available soil moisture by affording a ready exit for the solution of surplus salts.

2. Similarly the accumulation of salts in the form of an efflorescence at the surface is averted by drains which enable rains or irrigation floodings to wash them through into the deeper layers or an effluent channel.

3. The removal of gravitational water has the effect of substituting a slowly moving body of water for a stagnant accumulation. This is advantageous for several reasons. Soil water in motion has much greater dissolving powers than when at rest, and is, therefore, a more effective purveyor of plant nutriment. Again, stagnant or effete water loses its oxygen through contact with decaying organic matter, whereas fresh supplies are being continually introduced by a steadily moving stream. Being in a state of motion the water in a drained field facilitates the circulation of air within the soil and thus promotes the oxidation of those injurious compounds that occur in water-logged land. A further advantage in this connection is the free admission of rain, which not only warms the soil, but also brings to it appreciable quantities of nitrogen and ammonia. At Rothamsted it is estimated that approximately 5lbs. of nitrogen per acre per annum are derived from this source.

4. The better aeration of the land hastens the decay of organic matter, encourages the activities of useful organisms, and favors the complex series of changes that are collectively referred to under the name of weathering. In an atmosphere exhausted of oxygen, organic acids are produced, and as they accumulate the land becomes sour and unhealthy. With the introduction of fresh supplies of air, these are neutralised as they form, and the land is kept sweet.

5. Another very important change effected concerns the soil temperature. The two main factors that determine the distribution of crops throughout the world are soil moisture and soil temperature. By draining wet land the temperature is raised. King has stated that in early spring the differences in soil temperature at the surface between drained and undrained land may often be as great as 12 degrees F. Another authority found the temperature of a non-drained peat at a depth of 7 in., to be 47 degrees F., whereas in a drained portion of the same land the thermometer gave a reading of 66 degrees F., the difference in favor of the drained area being 19 degrees. By far the greater part of the soil's heat is absorbed from the sun, and unless the surplus water in a soil be reduced to a minimum, the energy of the sun's rays will, in the first instance, be spent in evaporating moisture instead of in warming the land. This involves a serious loss which is clearly reflected in the sluggish development of crops on our undrained humid areas during August and September. Apart from the fact that evaporation at the surface of the land tends to reduce soil temperature still further, the process is an unusually costly one to the farmer. Speaking to this point, Hall says that "the heat of the spring's sun may be largely spent in drying a soil without raising its temperature at all," and he goes on to state that "whereas the amount of heat required to raise a pound of water one degree would heat a pound of dry soil about seven degrees, it would take about 1,000 times as much heat to evaporate a pound of water, and even then no rise of soil temperature would result." The sun can only cause evaporation by convection currents, relatively a very slow process, whereas a cold wind cools a water-logged soil by conduction, which is much more rapid. The consequence is that undrained soils are easily chilled by cold winds, but are not readily warmed by sunshine. The temperature at which plants begin to grow and seeds to germinate is 41 degrees Fahrenheit, but a maximum rate of growth is not obtained by the general run of farm crops till the soil reaches a temperature of 70 to 80 degrees. The earlier this temperature is approached after the winter rains have fallen the better for the crop, and the only way to hasten the warming of the land in wet districts is to reduce the level of the ground water by drainage.

6. The physical condition of the soil is also improved by drainage, and the rootage zone is enlarged. The alternation of relatively dry and wet conditions favors the flocculation of the clay and the pulverisation and mellowing of the land to a considerable depth. The plant roots, in consequence, are

offered a wider and deeper field for development, and the lowering of the water table contributes to the same end. The practical effect of these changes is the cheapening and simplifying of tillage. The soil is rendered fit for cultivation, and will carry the farm teams earlier and more frequently in the winter, and there is less loss of time at seeding and in spring. It is most important that the land should keep warm during the autumn, since the success of crops in wet areas depends very largely on the progress they make at the beginning of the season. Similarly a quick start at the end of the winter is a wonderful help where summer rains are not to be relied upon.

7. Although land is admittedly made drier by drainage, crops grown on soils that permit free percolation will withstand droughts much better than those on impervious and saturated soils. The result of drainage is to lessen the total water content, but to increase the available moisture and enable the soil to store away increased quantities of reserved water. I would draw special attention to this, as in some districts one frequently comes across the notion that unless the land is water-logged during the winter there will be no growth in the summer. This is undoubtedly true where a thin covering of poor quality feed late in the season is the summit of one's expectation, but I do not incline to the view that the production of such small amounts of relatively innutritious "grass" marks the limit of fertility in these areas under a proper system of management. In years to come, when the surplus rainfall and under soakage have been brought under control there will be much less anxiety over dry spells than is felt at the present time. The increased amount of available moisture held by drained land, and the deeper rooting habits encouraged by depressing the water table will enable plants to thrive better under droughty summer conditions.

#### THE ADVANTAGES OF DRAINAGE.

To summarise, the advantages of drainage from the farmer's standpoint are—

- Heavier crops of improved quality.
- A better germination, thicker braird, and earlier harvest.
- A greater variety of crops may be grown.
- More clovers and a better quality grass appear in the pastures.
- Less risk of injury from inclement weather, disease, or pests.
- Easier and less costly cultivation.
- Manures and lime are made more effective.
- General health of livestock much improved.

Having pointed out the very real benefits conferred by drainage, it remains to consider how the work may be best carried out with due regard to economy and efficiency. In older countries under-drainage with tiles is preferred, but except over limited areas where the soil is of the highest quality, or in certain special cases, this system will prove too costly under our conditions.

Even in Great Britain recent writers affirm that the expense entailed is now practically prohibitive except on very high-priced lands. The total cost there per acre ranges from £7 to £12, and as the greater part of this expenditure is for labor, the figures for Australia would certainly not be lower. There is, however, a form of under-drainage by porous channels which may yet prove useful here for the better quality soils. I refer to sand drains which, it is asserted, can be made at about one-third the cost of tile drains. Machines are employed which excavate the channel, deposit the sand and close up the drain in one turn. It is estimated that 6 tons of sand are required per acre, and the sharper the material the more porous is the drain. Naturally, the amount of sand needed varies with the frequency and the dimensions of the drains. The former will depend on local conditions, and the latter will in general need to be four times the sectional area of an adequate tiled drain under similar circumstances. Where 3in. pipes would be used the sectional area works out the 7.06 sq. in. so that the sand layer in a porous drain of the same capacity would require to have a cross section containing 28-24in. This means, with a trench 5in. wide, sand would have to be laid to a depth of about 6in. A still cheaper form of under-drainage, known as "core drainage" may be effected by a similar machine. The work consists in cutting out a core of soil 3in. or 4in. in diameter at a depth of 2ft. to 3ft., and laying it on the surface. The system is applicable in the case of soils resting on homogenous clay subsoils, and also for peaty lands. The cost per acre is stated to be 10s., and in suitable land the channels are said to last for years. This system, or the somewhat less effective mole drain, are deserving of trial, for although the latter did not succeed at Kybybolite, the fault lay with the broken character of the subsoil, and not with the implement.

A good deal of the wet land in this State can be relieved of its surplus waters by a connected system of surface channels. Professor Wrightson instances a case in Gloucestershire where a whole farm was entirely drained on the open furrow system, without the use of a single pipe tile. "Merely by cleaning out and deepening the ditches which intersected the fields, such a complete circulation of water was induced that the whole intermediate ground was dried." It must be remembered that the effects of drainage are both gradual and cumulative. The land steadily improves in texture, and as the soil becomes more friable and crumbly it ceases to obstruct the downward flow of the gravitational water to the same extent.

I feel it incumbent upon me to labor this question of drainage, even to the point of monotony, as the future development of the districts concerned will be seriously retarded if the drainage of the land is neglected. Moreover, the recent praiseworthy movement amongst farmers in the Mount Gambier and other districts to procure ground limestone at a reasonable figure originated

at my suggestion, and I am, therefore, bound to indicate, in the clearest possible terms, that to go in for a wholesale liming policy on undrained water-logged soils will be wasteful in the extreme. Wherever gravitational water clogs the land for long periods drainage is the first desideratum, and the lime the second.

### REPLIES TO QUESTIONS.

In reply to questions, Mr. Colebatch said the question of added lime on most of the South Australian soils was one of neutralising the sourness. In work that had been carried out in other parts, it had been found that ground limestone of high quality was effective in this connection; but it was necessary to apply twice as much as would be applied in the case of burnt lime. When it was proposed to apply limestone marl, it was advisable to have the substance analysed, otherwise there was a danger of applying worthless material. The quantity of lime they would have to apply to the soil to sweeten it would be considerable in the first instance. They were dealing with the accumulated sourness of many years. Less than two tons of ground rock, going 95 per cent. to 98 per cent., would be of little avail. At Kybybolite they had dressed land with one ton of quicklime to the acre, and this quantity was not sufficient. In a general way, the dressing should vary between two tons and four tons. Experiments conducted in the locality suggested that good results would follow light dressings in the Wirrega and Tintinnara districts. Ground lime could be applied to the soil at any time, except when they were applying manure; quicklime should be put on two or three weeks before seeding. As to the matter of crops blighting through the application of heavy dressings of manure, he had never seen any blighting on any of the heavier class of soils which might be attributed to the effect of the manure. The trouble was due to extreme weather conditions. However, just how far they could increase the quantities of manures applied in the districts of light rainfall was a question yet to be determined. There were areas in the newly opened mallee lands which could well be given heavier dressings than were general. On the irrigation areas, and on very large areas in the wet districts of the State, they would have to adopt drainage systems, and surface drainage would not always meet the case. They could not afford to put in high-priced tile drains, therefore they should test the cheaper methods of underdraining, in order that they might ascertain whether these would suit the conditions. They had large quantities of sand in the South-East, which might be utilised in the way of sand drains. He did not think the land at Kybybolite, after being properly drained, would have sufficient humus to keep it in perpetual fer-

tility; but it would be comparatively easy to supply the humus. Stone drains would be satisfactory, if constructed of the right kind of stones; but in the South-East these were not available. He would not, as a rule, advocate harrowing crops on sandy, light soils.

#### VOTE OF THANKS.

This concluded the business of the Congress, and on the motion of Mr. Phillips (Meadows), seconded by Mr. W. B. Ashby (North Booborowie), a vote of thanks was passed to the officials, those who had contributed papers, and all others who had worked for the success of the Congress.

The Director of Agriculture, in the course of a brief response, said that it was a pleasure to prepare papers to read before such audiences as had assembled at the Congress. The officers of the Department did not, however, wish to take up too much time, as they recognised that many practical farmers were well able to bring forward important matters for discussion.

A vote of thanks to Messrs. Laffer, M.P., Coleman, and Birks, for having presided over the various sessions, was also carried, and Congress was concluded by the singing of the National Anthem.

#### EDITORIAL NOTE.

A temporary shortage of paper, due to the European War, has necessitated the curtailment in size of this issue of the "Journal."

Hence various Articles, &c., together with a number of Reports of Meetings of Branches of the Agricultural Bureau and the Report of the Conference of Hills Branches, have been held over; these latter will be published in an abbreviated form when circumstances permit.—[Ed.]

## IMPORTS AND EXPORTS OF PLANTS, FRUITS, ETC.

During the month of October, 1914, 1,877 bush. of fresh fruits, 12,120 bush. of bananas, 14,215 bags of potatoes, 1,198 bags of onions, 474 packages of vegetables, and 19 packages of plants, trees, and bulbs were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910. One hundred and ninety-four packages of bananas (over-ripe) were destroyed. Under the Federal Commerce Act 2,921 cases of fresh fruit, 1,615 packages of dried fruit, and 12 packages of preserved fruit were exported to oversea markets during the same period. These were distributed as follows:—For New Zealand, 242 cases lemons and 1,431 packages of dried fruit; for London, 40 packages dried fruit; for India four packages dried fruit and 12 packages preserved fruit; for South Africa, 140 packages dried fruit. Under the Federal Quarantine Act 411 packages (amounting to 59,581 lbs.) of seeds, bulbs, plants, &c., were examined and admitted from oversea markets.

## DAIRY AND FARM PRODUCE MARKETS.

A. W. Sandford & Co., Limited, report on November 1st—

**BUTTER.**—Values in the eastern States have been very stationary, and as South Australia is dependent upon importations for her shortage, our market is practically ruled by the rates prevailing there. Demand throughout the month has been rather quiet, the hot weather, no doubt, interfering with consumption. "Alfa" is selling at 1s. 2½d. per lb.; "Primus," 1s. 1½d.; secondary factory and creamery, 11½d. to 1s.; choice separators and dairies, 11d. to 1s.; store and collectors', 9½d. to 10½d. per lb.

**EGGS.**—Although extensive quantities have been reaching the market, the call both for local and export has been equal to the supply. Values show only slight fluctuations; hen are selling at 7½d. per dozen; duck, 8½d.

**CHEESE.**—Rates have improved, the warmer weather having caused a better inquiry for this line. Present quotations are 6½d. to 7½d. per lb. for large to loaf.

**BACON.**—Much heavier sales have been put through for October, both for local and export, but there is no quotable alteration in price. Sides, 8½d. to 9d. per lb.; hams, cooked 1s., uncooked 10d. to 11d.; middles, 10½d.; rolls, 8½d.; lard in skins, 8d.; bulk 7½d.

**HONEY.**—Only odd lots of last season's came to hand, and these were readily cleared locally at 3d. to 3½d. per lb. for prime clear extracted; beeswax, 1s. 2½d. per lb.

**ALMONDS.**—Last season's have all been placed, and buyers are awaiting the arrival of the new crop. Brandis, 8d.; mixed softshells, 7½d.; hardshells, 4d.; kernels, 1s. 7d. per lb.

**LIVE POULTRY.**—Extensive catalogues were experienced during October, and for all quality lots buyers operated freely. Good prices were secured, but a heavy proportion of the birds arrived in a poor condition. These met with a dragging sale and were difficult to place even at low figures. Good table roosters, 3s. 3d. to 4s.; nice conditioned cockerels, 2s. 3d. to 2s.; plump hens, 1s. 6d. to 2s.; light hens and poor conditioned cockerels, 1s. to 1s. 3d.; ducks, 1s. 9d. to 2s. 3d. for fair condition, no quality offering; geese, 3s. to 3s. 6d.; pigeons, 4½d.; turkeys worth 7d. to 9d. per lb., live weight, for fair to prime.

**POTATOES AND ONIONS.**—There has been renewed activity in the potato market and prices have further advanced. The Adelaide local crop of new, which at this time of the year usually contributes substantial supplies, is this year a disappointment, owing to dry weather conditions. Onions.—Importations from Victoria have supplied nearly the whole of our onion requirements. Present quotations are—Potatoes—Old, £6 10s. to £9 per ton (according to sample), on rails Mile End or Port Adelaide; new, 13s. per cwt. in the market. Onions—Old, £13 per ton, on rails Mile End or Port Adelaide; new, 16s. per cwt. in the market.

## THE WHEAT MARKET.

| Date.  | LONDON (Previous Day).            |                                                   |    |    |    |    | ADELAIDE    |

| 5      | Firmly held at full rates ;       | Liverpool firm, sparingly offered                 |    |    |    |    | Do.         |

In New South Wales the price of wheat as previously officially fixed was 4s. 2d. per bushel until October 16th, when the rate was altered to 4s. 6d. per bushel at Sydney and Newcastle, and 4s. 2d. for the rest of the State. At Melbourne and Fremantle the prices proclaimed remain at 4s. 9d. per bushel and 4s. 6d. per bushel respectively. The prohibition by the Commonwealth of the export of wheat has stopped chartering.

## RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of October, 1914, also the average precipitation to the end of October, and the average annual rainfall.

| Station.                   | For Oct., 1914. | To end Oct., 1914. | Av'ge. to end Oct. | Av'ge. Annual Rainfall | Station.               | For Oct., 1914. | To end Oct., 1914. | Av'ge. to end Oct. | Av'ge. Annual Rainfall |

\* No report received during the month of October.      † Formal report only received.  
 ‡ Held over until next month.

## ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

December 9th, 1914, and January 13th, 1915.

## THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

### REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

#### UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

WILMINGTON (Average annual rainfall, 18.26in.).

September 2nd.

Mr. H. Duhring read an interesting paper in which he gave some useful hints on care of mare in foal, and foaling. He would work a mare close up to the time of foaling, and then place her in a small paddock by herself, care being taken to see that there was no manure lying about. Close watch should be kept at the actual time of birth of the foal to render any assistance that might be needed. Mr. Duhring concluded by answering questions with reference to the actual action of foaling.

WIRABARA (Average annual rainfall, 18.9lin.).

September 5th.—Present: 22 members and two visitors.

DAIRYING.—Mr. J. Bowman contributed an interesting paper under this heading. To carry on dairying successfully, he said, one should select the best milkers possible and cross these with the Aryshire, Alderney, or Holstein. Stud bulls should be docile. They should be allowed to run with the herd only when required. Milkers should not be allowed to breed before they were 18 months or two years old, and young heifers should not come into profit until three years old, to do them justice. It was not wise to rear more calves than would keep the herd up, and they should be from the best cows only. Morning and evening milking should be carried out regularly. Hand milking was best. Holdings should be divided into, say, from 20 to 40 acre blocks, as stock did much better in this way than when running over large paddocks. Lucerne should be grown for summer fodder. If a good supply of water were available, irrigation was recommended. The milking shed should be built on the top of a rise, if possible, as in winter the water would drain away. For 30 milkers and upwards the shed should be 25ft. to 30ft. long, and 16ft. to 18ft. wide, the back and sides being built of stone or boards to within 2ft. of the roof, which should be of galvanized iron. This was much cleaner than thatch. The floor should be paved with bricks or blocks. The separating room should be built in the centre of the milking shed. After being milked the cows should pass through the shed into a small paddock at the back. This was much more satisfactory than backing them out. It was advisable to have the cowyard divided, and each milker should have the same cows. Milking and separating should be carried on at the same time, a small engine being provided to work the latter. Pig rearing was very profitable with dairying. The sties should be two or three chains away from the milking shed. Galvanized piping sufficiently large to carry the milk from the latter to the piggery should be provided, together with a large cask or small tank to receive same. A swing gate over each pig trough would minimise trouble and waste.

**ORBOROO, August 29.**—Mr. J. J. Dennis contributed a paper dealing with breaking in horses. He mentioned the essential nature of good tackling, and an abundance of patience, in connection with this operation. He detailed the method he adopted in handling the animal to be broken, and gave many valuable hints to the farmer who had young horses to handle.

**TARCOWIE, August 20th.**—**HOMESTEAD MEETING.**—The meeting was held at the homestead of Mr. D. Butterick. Crops of wheat, oats, and barley were inspected, and results of experimental work in cultivating and gardening were noted. All working horses were in good condition. Members were interested in some fine baconers and young pigs in Mr. Butterick's sties.

## MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

**BOOLEROO CENTRE** (Average annual rainfall, 15.83in.).

September 25th.—Present: 17 members and two visitors.

**SHEEP.**—Mr. W. H. Nottle, sen., read a paper in which he stated that his experience had proved that the Merino was the best sheep for this district. This animal returned a more valuable fleece, and was less difficult to control than other breeds. Fat lamb raising was not payable, except in very good seasons; therefore, to attempt this industry was unwise. On the other hand, dry sheep practically always met with a good market, and he thought dry ewes usually kept their condition better than wethers when there was a shortage of feed.

**GLADSTONE** (Average annual rainfall, 16in.).

August 29.—Present: 14 members and one visitor.

**HAYMAKING AND CURING.**—In a paper dealing with this question, Mr. J. S. Fisher said the best time to cut wheat for hay was a few days after the flower had fallen. If the crop were to be stacked immediately, he would put five tips of the binder into each stook. For quick drying, long, narrow stooks were best, but generally he preferred the round stook, made up of seven or nine tips of the binder. The centre sheaves should be placed upright, and the outside sheaves should have a considerable lean toward the centre. By placing the first sheaf in each stook on the mark of the large binder wheel, carting would be considerably facilitated. If the hay were on the green side, and weather conditions were unfavorable for drying, it was preferable to allow it to lie for a day or two. To determine whether the hay was fit for stacking, a few straws should be pulled from the centre of a sheaf in the middle of the stook; if these would break off short at the nodes when bent, stacking could be commenced. It was essential to build the stack with the centre higher than the sides, to prevent the ingress of water. It should be wider at the eaves than at the bottom, and should have a foundation of 6in. or 8in. of dry straw. He then described the method he adopted in stack building. In the event of a fall of rain on the unfinished stack, he advised sprinkling coarse salt on the wet hay. An essential factor was to place the sheaf in the stack with a droop outwards.

**LEIGHTON** (Average annual rainfall, 16in. to 17in.).

October 3rd.—Present: 15 members and two visitors.

**ENGINES ON THE FARM.**—In a paper dealing with this subject, Mr. H. G. Oates advised the farmer who required an engine for continuous running to purchase an oil engine, but the man who only required to chaff about 80 tons of hay, would most likely find the petrol engine most satisfactory. The latter, which was run with a high tension magneto, gave less trouble than an engine with a low tension magneto and batteries. The horizontal type was preferable to the vertical, as it was better balanced, and the crank did not carry the dead weight of the piston. Fairly large flywheels, of which he preferred two on an engine, helped to maintain an even speed. Where the work could be done from one centre, stationary engines would be found more satisfactory. Messrs. A. E. McWaters and S. Cordon preferred the oil engine, whilst Messrs. R. McWaters, R. Fairchild, and M. Hogan recommended the petrol engine.

**NORTH BOOBOROWIE (Average annual rainfall, 16.35in.).**

September 16th.—Present: 15 members and 25 visitors.

**WOOL-CLASSING.**—Mr. Henshaw Jackson, the Wool Expert, gave an interesting demonstration in wool classing. He advised those who had 200 sheep to shear to class their clips into three lots, the top lot to consist of all well-grown, sound, bright, light, fine-quality fleeces, with staple of 2½ in. or longer. The bales containing these should be branded A Mo. The second class would contain fleeces of strong quality, sound, and staple same as A class; this class should be branded B Mo. The third class would contain fleeces of shorter staple, heavier in condition, and varying quality, and all tender fleeces, and branded Mo. Should there be any very heavy fleeces these should be placed aside and put into a bag.

**PORT BROUGHTON (Average annual rainfall, 14.44in.).**

August 28th.—Present: 10 members and two visitors.

**PREVENTION OF SAND-DRIFT.**—Mr. A. J. Fletcher read a paper on this subject. On small patches the application of manure, or even straw, was effective in checking sand-drift, he said, and in extreme cases afforestation could be resorted to. For this district, he considered cultivation would be found to answer best. All rubbish should be ploughed into the land, but where the stubble was too thick and strong to permit of this, he would use the rake, and then burn off, afterwards turning it in. The sand should only be worked when wet, and then east and west. Tomato bush, stinkwort, &c., would be turned in by the autumn fallowing; this was consequently less liable to drift than winter fallow. In the discussion Mr. T. Pattingale said that spring working being the principal cause of drift, he would use the cultivator in preference to the plough, and would not harrow the hills. To prevent drift during seed time, he would work straight along the hills. Messrs Whittaker, G. Pattingale, G. Routley, and a visitor also took part.

**REDHILL (Average annual rainfall, 16.79in.).**

August 11th.—Present: 14 members and three visitors

**BREAKING COLTS.**—This subject was dealt with in a lengthy and interesting paper by Mr. J. Potts. He described in detail the method he adopted in handling young horses, emphasising the necessity for kindness and firmness. He favored catching the animal to be broken with the whip in preference to the crushpen or rope. Members favorably discussed the paper.

**SPALDING (Average annual rainfall, 20.25in.).**

September 18th.—Present: 10 members.

**SOIL FERTILITY.**—The following paper on Soil Fertility, was read by Mr. A. B. Jones:—"The yield of wheat on virgin lands is invariably greater than that obtained from land under cultivation for several years, even when the cultivation of the latter has been thorough. The fertility of the soil has been diminished by frequent cropping. In older agricultural countries farmers have to expend large sums of money on artificial fertilisers to replenish the severe drain that has been made on the plant food in the soil, and likewise the soils of this country are not going to answer for an indefinite period the calls we continue to make on them by the practice generally adopted of alternating crop and fallow. If means are not taken to prevent the diminution of the natural fertility, the time is not far distant when farmers will realise that the addition of superphosphates alone will not give the yield the land returned during the first years of its cultivation. The expenditure of money for manures, other than phosphatic, should scarcely be required if the bacterial fertility be maintained, as it is more economical to maintain the natural fertility than to apply artificial manures. The system of thorough fallowing now generally practised is burning out the organic matter, and the decline in the crop-producing power of many soils is due to loss of humus; and this deficiency renders many soils not lacking in plant food unable to produce satisfactory crops. This loss or deficiency is more serious in dry districts than in regions of heavy rainfall. The useful bacteria of the soil are most active when the land is in a warm, moist state, and a plentiful supply of humus is essential for the continuance of these conditions; and the thorough working of the land, by reason of the aeration, and conservation of moisture, is conducive to bacterial activity. The farmer on "new" land, which has

a reserve of humus, is quite justified in taking wheat crops from it as frequently as he can do so, that is by alternating crop with fallow, for a few years, or even sowing the same ground for several successive years; but let the occupier of land farmed for a number of years in this fashion attempt the same system, and he will find the result disastrous. The question of maintaining this supply of humus, which is of such vital importance to soil fertility, is now of great importance to all holders of hard-worked lands. The general idea, apparently, is to work the land on the three-year system, i.e., fallow, wheat, and grass. By this means the straw from the wheat crop is brought to a suitable condition for ploughing under, and the droppings from the livestock grazed on the land during the period it is under grass also materially assist in supplying humus, besides assisting to maintain the necessary plant foods of the soil. Farmyard manure carted out and spread over the land, to be afterwards worked in, is another much neglected, but very valuable, source for maintaining soil fertility, and if the value of it were fully realised one would not see the heaps, in some instances covering acres of ground, lying about the paddocks. Another source of humus is in the growth of fodder crops, to be either grazed off or ploughed under—the latter is generally known as green manuring, and is a most prolific source of organic plant food. Perhaps this method (the growth of fodder crops) will prove the best for keeping our lands in a highly productive state."

#### WHYTE-YARCOWIE (Average annual rainfall. 13.9in.).

September 3rd.—Present: nine members.

**BREEDING AND FEEDING HORSES.**—A paper under this heading was read by Mr. F. Hunt. For farm work he would breed from half or three-quarter bred, well shaped, and moderately large mares, and a pure-bred stallion. Horses thus bred would cover quarter of an acre more per day than the lighter class of animals. It was best to pay a good service fee and obtain the services of a good stallion. The mares should be as sound as possible, as any bad points would probably be handed down to the foals. He would work the mare lightly right up to the time of foaling. When the foal was being weaned it was wise to keep it out of sight and hearing of its mother, and to place it in a yard with another foal to discourage fretting. He emphasized the value of properly feeding the foal. The supply should not be stinted, neither should stale food be left in the manger. Good hay chaff, with a little bran should be given, starting with small quantities. Where sufficient hay to last 12 months was not available, it was wise to conserve the cocky chaff and straw, which, mixed with molasses, made good feed. For working horses he recommended chaff and oats, but the oats must be crushed to ensure their being digestible. Members generally agreed with the remarks having reference to feeding. They preferred breeding from the best mares they could secure, as good draughts always found a more ready sale than the half-bred animal. One member considered five sheaves of hay fed to young horses as good as six sheaves cut into chaff, as it was more thoroughly chewed, and kept the young animal's teeth in better order.

**LEIGHTON, August 29th.**—"THEFT."—Mr. R. J. Fairchild read a short paper on this subject. On every farm, he said, there was room for economy. In the purchase of supplies, machinery, &c., much care should be taken. Working plant should always be kept in good order, and paint applied where needed. Keeping old and practically useless stock was a mistake, and so also was over-feeding. The floor of the chaffhouse should be concreted all over. The farmer would then save the short stuff that fell from the sheaves. To be successful the farmer needed to be industrious, ambitious, and tactful. Messrs. J. McDonald, A. E. McWaters, S. Cordon, J. Hogan, and T. P. Goodridge agreed with the writer of the paper.

**MOUNT BRYAN, October 3rd.**—A paper dealing with co-operation amongst farmers was read by Mr. E. Thomas. Members discussed the question at considerable length.

**MOUNT BRYAN EAST, September 26th.**—A short paper on the care of farm harness was read by Mr. V. Hughes. He preferred the pipe collar for working horses, and recommended that this should be restuffed at least once a year. If the leather was protected from wet weather, its life would be considerably lengthened.

**NORTH BOOBOROWIE, September 28th.**—The Veterinary Lecturer (Mr. F. E. Place, M.R.C.V.S.) was present at this meeting, and gave a practical demonstration. After having prescribed for a number of horses and performed a few operations, he dissected an aged gelding (supplied by Mr. L. D. Clark), and explained to members the functions of the various organs, &c. In the evening Mr. Place gave an interesting lecture on flatulent and spasmodic colic.

**PORT BROUGHTON, October 2nd.**—Papers read at congress were discussed, particular interest being taken in the paper on "Demonstration Plots—Mixed Farming Areas," by Mr. H. V. Sprigg, of Morphet Vale Branch. Mr. Pattin-gale remarked that his crop of rape was very poor this year. Mr. J. H. Fletcher (hon. secretary) explained how experimental plots were conducted at the Roseworthy Agricultural College. Members had noticed that real limestone ridges had done better than the sand this year, but did not think liming would pay in this district.

## LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

**BALAKLAVA** (Average annual rainfall, 16.03in.).

September 19th.—Present: eight members.

**CONSERVATION OF FODDER.**—A paper on this subject was read by Mr. O. Uppill. Cereal hay, he said, could often be cut and stacked, instead of, as it was in some cases, left to rot or blow away when dry, or possibly burned by way of cleaning the land. Oaten straw, if cut behind the harvester and stacked, made good clean fodder. Oats could be grown very cheaply on stubble land in a good season and cut for hay. In a good season a portion of the wheat crop should be cut with the binder and headed, which could be done at approximately 15s. 6d. per ton, which would work out as follows:—The average crop that would yield 19bush. of wheat would produce 1 ton of headed straw and cocky chaff. Cost of binding one acre, 3s.; twine, 2s. 6d.; stacking, 3s. 6d.; restacking, 1s. 6d.; extra cost of cleaning and heading compared with the complete harvester (9d. per bag), 3d.—1s. 6d.; one bushel to the acre waste, 3s. 6d.—total, 15s. 6d. The crop should be cut from seven to 14 days before ready for stripping, according to the conditions under which it was ripening. Mr. Spillane said there had been thousands of tons of material that might have been conserved as food for a season like the present, wasted. Heading would be best. The headed straw could be mixed with good hay. Mr. Reid thought the expense of a header and the cost of running it might affect the wisdom of this scheme. Mr. Butler said headed crops had been known to yield 2bush. to the acre more than the remainder of the crop, which had been left to be taken off in the ordinary way. Mr. Tuck said oaten straw was very useful for fodder. He had headed wheat and chaffed the straw, and when a little oats was mixed with it in summer, the horses did well on it. The best time to cut the crop for heading was just as the husk was getting white. The early varieties of wheat were the best for this purpose. Mr. Roberts remarked that by cutting with the binder they lost a lot of green picking which came up in the stubble of reaped crops.

**GAWLER RIVER** (Average annual rainfall, 17in. to 18in.).

August 3rd.—Present: 13 members.

**FARM MACHINERY.**—A discussion on this subject was initiated by Mr. C. Leak. Owing to the price of labor, and uncertain returns, he said, it behoved farmers to exercise great care in working their farms. This specially applied when purchasing machinery and implements. It was a mistake for the small farmer to purchase implements that necessitated his procuring extra draught, as small holdings did not warrant keeping large teams. When not in use the implements should be kept under cover, and the woodwork given a coat of paint. He instanced a case where one farmer secured eight years' work from his binder through careful handling and attention, while another's binder was useless after three years' work, simply because no care had been taken of it. Mr. Winckel considered cutting too close to the ground harmful to a binder.

Mr. F. H. Dawkins would oil the bearings of his machines when working sandy soil. When working the binder or harvester Mr. W. Biechter always endeavored to cut straight across any sandy ridges, to lessen the danger of the machine dropping to one side, and thus throwing sand into the bearings. Members generally considered that the condition of the land had a great influence on the life of farm machinery, last season being very heavy on it, owing to the dusty and sandy state of the soil.

NANTAWARRA (Average annual rainfall, 15.90in.).

September 4th.—Present: 11 members and one visitor.

HORSE-BREEDING.—Mr. Smith read a short paper on this subject. He thought it a mistake for farmers to refrain from mating their mares on account of the bad season. With one or two good years he considered that horses would bring a very high price, as there had been a big reduction in the number in this State through the drought, and also on account of new country being opened up. Men breeding draught horses at the present time were acting wisely, as, when the prices of horses rose, they would be in a position to sell. In the discussion which followed Mr. Sutton agreed with the writer of the paper that it was wise to continue mating mares during the drought, to meet subsequent demands. Mr. Sleep considered it advisable to breed for one's own use only. Mr. J. H. Nicholls thought that the risk of losing both mare and foal did not warrant breeding during bad seasons, whilst Mr. Dixon would continue breeding. Where the prospects of a grain yield were bad, the brood mares could be turned in on the crops. Mr. A. F. Sherbert said that horse-breeding had always paid him well, but he only intended to have a limited number of mares served this season. Mr. R. P. Uppill considered it would be detrimental to the development of newly-opened areas if horse-breeding were seriously retarded on account of the drought.

MALLALA, October 7th.—The meeting was held at the homestead of Mr. J. Nairn. After inspecting the building, and a fine crop of Gluyas wheat, the meeting took the form of a question evening, which was the means of bringing out the following useful information. In average years late wheats give the best returns. Members who had had experience with this food favored feeding molasses to stock. Gluyas was considered the best drought-resisting wheat. It was resolved that the district council be asked to distribute poisoned wheat amongst farmers, free of charge, for the destruction of sparrows.

## YORKE PENINSULA DISTRICT. (TO BUTE.)

BUTE (Average annual rainfall, 15.42in.).

September 29th.—Present: 13 members.

FARMYARD MANURES.—Mr. S. Trengove mentioned that he had found that manure carted from the stables direct on to sand, had not a very beneficial effect, especially in very dry seasons, as it caused the crop to burn off when dry winds were experienced. Mr. A. Schroeter had found stable manure, placed on land for green feed or fodder, return good results, especially when the applications were made to sandhills. He strongly favored applying stable manure to land for fodder or hay crops. Mr. W. Sharman said the manure should be allowed to rot before being placed on the land. Mr. R. W. Herbert would apply heavy dressings to land carrying such crops as mangolds, but not in the case of wheat or other grain crops. Generally members favored applications of stable manure to land for fodder and hay crops, but not where grain crops were being grown.

FODDER CONSERVATION.—Mr. A. Schroeter said that owing to the scarcity of hay this season it would pay farmers who had crops sufficiently long to cut some for heading. Members generally agreed that the straw so obtained would be valuable for fodder purposes. Mr. Herbert mentioned that he had grown a considerable amount of rye, and the straw of this mixed with oaten hay, had made very good stock feed.

ARTHURTON, September 2nd.—Members discussed whether hoarhound should be placed on the list of noxious weeds, and finally decided that this plant was not likely to do much harm. Some members mentioned its valuable medicinal qualities. The condition of the crops in this district was discussed, and it was generally considered that although they had suffered severely during the last month, a good rainfall in the near future would ensure a fair return.

MAITLAND, October 3rd.—The meeting was held at the homestead of the president (Mr. E. G. Jarrett, and took the form of a social evening. Mr. H. G. Tosell, on behalf of the Branch, presented life certificates to Messrs. Bawden and Hill. The long and useful services of these two gentlemen were mentioned with eulogy.

MINLATON, October 8th.—A short paper on "Farm Labor" was read by Mr. D. McKenzie, and discussed by members. The desirability of conserving chaff, straw, cocky chaff, &c., for feed during the coming harvest was considered. Members agreed that special efforts in this direction should be made, as in many cases farmers in different parts of the State would have neither crops nor feed this year, and would be glad of any surplus feed that might be available in other places.

## WESTERN DISTRICT.

### CARROW.

September 26th.—Present: nine members.

SORE SHOULDERS.—Mr. F. J. Annear read an interesting paper on this subject. Before commencing work, he said, care should be taken to see that all the horses' collars fitted correctly. He preferred leather-lined collars, as, when dirty, these could be easily cleaned with soap and water. Piped collars gave freedom to the windpipe, and the horses were therefore less liable to choke down in the hot weather than with round collars. Every collar should be occasionally beaten with a bottle or stick to loosen and soften the stuffing. Continuing, the paper read:—"It does not always happen that faulty collars are the cause of sore shoulders. Sometimes a horse will get overheated through eating food which is not suitable, or get a sudden chill, either of which may cause small pimples or blisters on the hide, and the collar will take the tops of pimples off, which, if not attended to at once, will result in sore shoulders. In a case of this kind all grain must be kept out of the horse's feed, and sores washed first with a very weak solution of carbolic soap, and then clean lard, free from salt, applied to affected parts. When a sore shoulder appears to have been caused by the friction of a collar, and is clean and healthy, washing with warm water night and morning, and a plentiful application of either pure lard or coachalaine, with a dusting of boracic acid, will be found very effective. The collar stuffing in the vicinity of the sore should be worked away. The hollow should be of sufficient size, as if the collar is only hollowed around the sore, the soft, wounded flesh becomes forced into the hole, and it will not heal as quickly as it should. Another good idea is to sew pads of curled horse hair above and below the sores. In the case of a sore of long standing, where the wound has become suppurated, and the flesh poisoned, the horse should not be worked for a while (say three days). The wounds should be first cleansed with hot water, then washed with a good solution of bluestone or carbolic, and any parts of decayed flesh, which will not wash off, cut out with a piece of bluestone. To do this take a piece of bluestone and hold it to the flesh, frequently wetting and cleaning away the impurities which will run on to it. After the wound is thoroughly clean, and the flesh bright, apply the following ointments:—1. Pure lard (free from salt), seven parts, and Friar's balsam one part. The horse can be worked while this application is being used, but a spell of three days is beneficial, to give the cure a start. 2. Bathe affected parts with mixture of 1 pint warm water,  $\frac{1}{2}$  pint tincture myrrh. Dress with solution of common salt,  $\frac{1}{4}$  lb., in half-pint of water, to which is added quarter bulk of Friar's balsam. When sores become hard, and

appear like warts, apply a mixture of seven parts pure lard to one part red iodide of mercury, well rubbed in. If warts do not disappear in five days, repeat application. The horse should be worked, and pure lard should be put on parts affected each day for five days, and if not then fully cured, make a further application of lard and iodide of mercury. Another cure is to wash the shoulders in hot water with tincture of Friar's balsam, 2ozs., compound tincture myrrh and aloes, 2ozs. Use the mixture three times daily. Put it on the shoulders while working; or linseed oil 12 parts, glycerine five parts, carbolic acid three parts. Apply three times daily with a feather.

#### ELBOW HILL.

August 29th.—Present: 10 members and two visitors.

**AUTUMN FALLOWING.**—In a paper dealing with this subject, Mr. F. Freeth mentioned that the spare time after harvest could well be utilized in fallowing. After each fall of rain the harrows should be used, and after seeding, the scarifier. Following this, the harrows and then the roller should be put over the land. The scarifier should then be used to destroy the weeds and work the fallow. He had practised this system with considerable success. A good discussion followed the reading of the paper. Messrs. E. and S. W. Wake favored early fallowing, and Mr. H. Wheeler preferred autumn fallowing. Mr. Zerk was of the opinion that autumn fallow, worked in the winter, would be conducive to "take all" in this district, as the rain was insufficient to consolidate the soil. Mr. Dawkins had noticed the value of well-worked fallow. Wheat sown late on stubble land had not germinated this season, whilst that sown on fallow was looking as well as could be expected for the dry season. The chairman (Mr. W. G. Cooper) was in favor of autumn ploughing and winter working. The hon. secretary (Mr. G. F. Wake) emphasized the importance of properly working the soil before sowing.

**FEEDING SALT TO SHEEP AND STOCK.**—Mr. Freeth then read a short paper dealing with this matter.

#### MITCHELL.

September 5th.—Present: 17 members and eight visitors.

**SHEEP ON THE FARM.**—This subject was dealt with in a paper by Mr. J. H. Vigar. He stated that three essentials to success were good breeding, good feeding, and care. Sheep should have the wool cut well back from round the eyes, and crutching should be done just before the lambing season and again before shearing. For this district he advocated the Lincoln-Merino cross. A flock of young, well-bred Merino ewes should be obtained, together with one Lincoln ram to every 50 ewes. The ewes should be secured, if possible, from a colder district than the one to which they were to be brought. The rams should be changed every two years, first using the Merino, and then the Lincoln. The Shropshire or the Dorset Horn, he said, was a good mutton sheep, but did not give a very large fleece. Lambs should be dropped from March to the end of May, or even into June, and for this district he advocated late lambs, say from May to August. This enabled them to get a good start on green feed. A flock of 100 ewes should, in 12 months, return an average of 8lbs. of wool. This at 9d. per lb. represented 6s. per head, or a total of £30. This flock should also produce, say, 80 lambs, and half of these put on the market off shears at 9s. each would bring in £18. The cut from all the lambs should average 2lbs. at 9d. lb.—£4 13s. 4d.—making a total return of £52 13s. 4d., and apart from this profit, the flock would be increased by 40. Members generally, in discussing the paper, agreed with the writer. Mr. Trimble considered 1 per cent. of rams quite sufficient, but Mr. S. Baker advocated a larger percentage of rams than was mentioned in the paper to ensure a shorter lambing season.

#### ROBERTS AND VERRAN,

September 29th.—Present: eight members and one visitor.

**BREEDING FARM HORSES.**—A short paper was read on this subject by Mr. C. Kunst. He preferred the horse with clean legs, good body, plenty of weight, and yet plenty of life. This class of animal could be produced by mating a good draught mare with a blood stallion. Another good style of farm horse was bred by mating the blood mare with a draught stallion. The foal from this union would be thick set, round-boned, be a good worker, and easily kept in condition. It was

necessary when breeding to see that the mare was good tempered and that the stallion had secured the Government certificate for soundness. In discussing the paper Mr. G. Plew stated that he would breed a heavier class of horse for farm work than that suggested by Mr. Kunst, and Mr. L. Cowley and Mr. W. Sharman were also of the same opinion. Mr. W. Kunst favored breeding from young stock only, the mares to be good tempered; but Mr. McCallum considered that by breeding continually from young mares the stock would become too slow for farm work.

#### YABMANA (Average annual rainfall, 15.14in.).

August 29th.—Present: 10 members and two visitors.

**HAY WHEATS.**—A paper under this heading was read by Mr. M. K. Frost. Slow-growing, soft-strawed varieties, he said, more than compensated for what they lacked in weight, by their wheat-yielding qualities, should they be too short to cut for hay, and by their intrinsic value. Hard-strawed, quick-growing varieties, if a failure for hay on account of short straw growth, were practically useless to reap for wheat. He recommended Yandilla King, Silver King, and Marshall's No. 3 as the best of the slow-growing, soft-strawed varieties, and for hard-strawed, fast-growing varieties, suitable for hay, he recommended Majestic, Gluyas, Comeback, and Tuscan. The slowness of growth in the soft-strawed varieties was only apparent during the winter months, and from the beginning of spring their growth was very vigorous and rapid, so that they arrived at the hay-cutting stage very soon after some of the fast-growing sorts. He recommended Gluyas for both hay and grain for areas of little rainfall, as this variety was a good drought-resisting wheat, but for districts of good rainfall he recommended the soft-strawed wheats. In discussing the paper Mr. A. Robertson said he favored Gluyas, which he had found made excellent feed if cut just as the flower was going off. Mr. A. D. McCallum favored Marshall's Hybrid for hay, which yielded a heavy crop, and could be cut when the grain was starting to firm. It was also a splendid drought-resister. Mr. J. F. Robertson favored soft-strawed varieties, and recommended Golden Drop for hay. This type made good chaff, was of good color, and weighed well. Mr. G. W. Story had sown Gluyas and Marshall's No. 3 in equal quantities for hay. The Gluyas being early, made plenty of grain in the chaff, while Marshall's No. 3, being late, made the chaff a good color. Horses preferred chaff cut from this mixed hay. The chairman had had to fall back on the Gluyas, as frequently the soft-strawed varieties had not warranted cutting. For hay the Gluyas should be cut green, just as the flower was going off. In replying to the discussion Mr. Frost stated that he had had no experience with the Marshall's Hybrid. He would not favor Huguenot, as it required very thick sowing, and gave a very poor wheat yield. If hay was intended for sale it should not be cut until the grain was well developed, but if for his own use he would cut just as the bloom had gone off. Members generally agreed that a crop cut just as the grain was between the "milky" and "doughy" stages, was of the best feeding value. The majority of members considered from three hours to half a day long enough for the hay to be left before being stooked. Oats should be cut when the straw was of a good, pink color.

#### YADNARIE (Average annual rainfall, 14.09in.).

October 3rd.—Present: 17 members and two visitors.

**EXPERIMENTAL WORK.**—Mr. A. A. Jericho read a paper on this subject. The majority of farmers, he said, were not sufficiently keen on experimental work carried on in a businesslike manner. Frequently men would drill in adjacent strips of land with different quantities of manure, and remark when stripping that they "didn't notice any difference." A payable difference would not be noticeable in a 6-bushel crop if the strips were not harvested and weighed separately. If every farmer conducted tests on several one-acre plots each year, the knowledge gained would be of lasting value. The plots could be pegged out on either side of the paddock, and ploughed in one land. Only the drill and reaper would have to turn on each plot; thus very little extra time was involved. Government experimental farms in settled districts were not justified; but these were valuable in new areas as a guide to settlers. He advised the Branch to set aside one meeting in each year for members to relate the experiences of their twelve months' work. An interesting discussion followed the reading of the paper.

**YALLUNDA** (Average annual rainfall, 18in. to 19in.).

October 3rd.—Present: 10 members and two visitors.

**MIXED FARMING.**—A paper on this subject was read by Mr. J. S. Perry. Where holdings were small, he said, it would be more remunerative for farmers to practise mixed farming than to grow cereals alone. A few sheep, cattle, pigs, poultry, or bees, or even a fruit and vegetable garden, made payable side lines. He should endeavour to market his produce between May and August, when there was the most demand for it. Cows should come in about April to have the advantage of the early feed. He stated a case where one farmer had sold 40lbs. of butter per week, when the price was over 1s. per lb. He advised sowing small plots of lucerne, barley, and rye for green feed. Fowls should be hatched at such a time that they would be laying in about April. Ducks, geese, and turkeys could be reared and fattened for market. If sheep were kept, summer fodders should be grown. Sorghum and rape, sown on fallow and favored with good summer rains, made splendid feed for sheep. Fruit and vegetables should do well in this district, and every farmer should grow at least enough for his own use. Bees, also, could be kept at an advantage. Members discussed the paper, and experiences of this method of farming were given.

**CARROW**, October 13th.—The Director of Agriculture (Professor A. J. Perkins) and the Secretary of the Advisory Board (Mr. G. G. Nicholls) were present, and addressed the meeting, which was attended by members of both the Carrow and Butler branches.

**COORABIE**, August 29th.—An article on horses eating wheat was read. Members agreed that carbonate of soda constituted a good remedy, but did not agree with waiting for symptoms when it was known that a horse had been gorging itself with wheat.

**ELBOW HILL**, October 3rd.—Mr. A. Dawkins read a paper dealing with the working of a Branch of the Agricultural Bureau, and gave many valuable hints in this connection.

**GOODE**, September 9th.—The meeting took place at the farm of Messrs. Morcombe Brothers. The growing crops were inspected. A paper on fencing was read and discussed in the evening. Mr. J. Nicholls recommended the plough for trenching to let in the wire netting. Mr. P. Morcombe thought the posts should be of uniform height, with the barbed wire placed along the tops. Mr. C. Will considered netting the best subdivision sheep fence, and Mr. W. Tainsh advised making the droppers of teatree.

**KOPPIO**, September 3rd.—Members were of the opinion that at times when prices of barley and oats were low, it was more profitable to feed same to sheep. Mr. Jericho had fed 2lbs. of oats per head per day to sheep, which were kept in a small yard, and although in a very low state when yarded, at the end of a month they were in a good marketable condition.

**KOPPIO**, October 1st.—The School of Mines Wool Expert (Mr. Henshaw Jackson) gave a demonstration in skirting, rolling, and classing wool.

**MILTALIE**, October 3rd.—Mr. L. Aunger read a paper on "Economy on the Farm," which contained many hints on how expenses could be curtailed and the yearly income increased. He emphasised the value of keeping one or more side lines, such as poultry, cows, &c., on the farm, which would bring in a steady return, and prove to be a great boon in years such as this, when the wheat crop was a failure. Members discussed the subject, and their ideas thereon were in sympathy with those of the writer of the paper.

## EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

**CLAYPAN BORE** (Average annual rainfall, 16in. to 17in.).

August 3rd.—Present: 12 members and one visitor.

**BREEDING AND MANAGEMENT OF FARM HORSES.**—The chairman (Mr. J. Gray) read a paper on this subject, in which he said:—"The question as to whether it pays to breed farm horses, when one can buy them more cheaply than they can be reared, is one that is often heard at the present time. In answering this, it is well

to remember that we are now passing through a time of severe agricultural depression. The last two years have pressed heavily on most of the now mallee districts, and have thus restricted settlement, and consequently there has been little demand for horses. These factors have combined to depress the market. When normal seasons return there will be a rapid expansion of settlement in the new areas being opened up by railway extension. For this a large number of horses will be required. It will probably also be found that a large number of horses have been killed off by the drought, and even some of the northern farmers may have to come into the market to replace losses. Then it must also be remembered that for some time there has been a steady export trade of the best-quality horses to Western Australia, and last, but not least, owing to the high prices prevailing, and likely to prevail, for beef, many station-owners who now breed draught horses will turn their attention more to cattle-breeding. There is another matter, too, that must not escape our notice in this connection. When there is an upward tendency in the horse market and there is plenty of feed in the paddocks, hundreds of horses get into dealers' hands, and are held for speculative purposes. Taking these things into consideration, the market for horses, we may be assured, is not going to remain in its depressed state any longer than the present drought conditions remain. The foals of to-day, I confidently expect, will be worth payable prices when they are fit to break in. Though horses are cheap now, money is scarce, and my experience is that it is very nice to have a good-quality colt or filly to break in to fill a gap in a team without having to buy it. Look at the matter from another view-point. Take the working life of a horse as ten years. (If I based my estimate on my own experience I should say twelve years.) After paying for his keep, £3 per year will be a low estimate for a horse to earn as a sinking fund to stand against his value or actual cost. Thus, at three years old a good-quality colt, with his working life of ten years before him, will be worth £30. (Draught horses in the Adelaide market are quoted at from £25 to £30.) This will give the farmer about £10 per year for rearing a draught colt or filly. This, I think, will pay, providing, of course, that the cost of getting the foal is not too heavy. The foal will earn nearly as much as a worker on the basis of my estimate.

*Cost of Service.*—The cost of getting the foal is a very serious item with many farmers. In patronising stallions that travel the district, say with five to seven mares it has cost me as much as from £7 to £10 per head to get the foals, besides the loss of time in attending to the mares when the stallion visited the farm during the season. In any case, the cost usually works out around £4 per head. I am referring, of course, to the number of mares that are put to the stallion, but do not prove to be in foal. The blame is usually laid on the stallion. Experience on our farm, however, proves that all the blame should not be laid on the stallion. There are many contributing causes. On the mare's side at the time of service there is overwork, want of condition, or poor feed. I believe, however, the trouble lies principally in the fact that the mare is not mated to the stallion just at the right time. It is reasonable to suppose that if the stallion only comes to the farm once in ten days all the mares will not be in the proper condition to receive the horse. Some mares are very much more easily stunted than others, and these are the only mares that are profitable to put to a stallion that travels the district. If a farmer has four mares from which he wishes to breed, it will pay him to keep a stallion of his own, unless he can make a convenient arrangement for his mares to be served by a horse kept on a neighbouring farm. A suitable horse can be obtained for the price, say, of two colts. (At the present time for 40 to 50 guineas.) This class of horse can be made to do all kinds of farm work, and thus will take the place of a good horse. If there is a loosebox with a small yard attached; or, better still, a small paddock, which can be cultivated, where he can run at large and during spring time get most of his living, the attention he requires will be reduced to a minimum. Experience on our farm shows that if the stallion is not travelling a round of any extent, better results are obtained by working him three or four days a week during the season. When a stallion is kept on the farm, not only is there the advantage of having him on the spot to use at discretion, but there is also a great deal of time saved, as against waiting upon a travelling horse when he is brought to the place. Another debatable point is the class of horse most suited to this district. On most farms there is a great deal of heavy sand for horses to work over, and some people argue that consequently the lighter class of horse with a little of the blood horse in him would be more suitable. It must be remembered, however, that where

there is heavy sand there will of necessity be heavy hauling in the carting of wheat and hay. The lighter stamp of horse is, generally speaking, not the most reliable for a heavy pull—his high spirit is against him in that respect. Experience again goes to show that a good, strong, weighty draught horse will stand travelling over sand and be ready for a heavy pull when required. I do not think there is much fear of the average farmer in this district breeding horses that will be too heavy for this class of country. And if he happens to do so, he can safely go ahead, for there will always be a good demand for extra heavy draughts for road work. This class of horse can be sold and replaced by a lighter one at a good profit.

*The Stallion.*—The most important thing in the breeding of horses is the selection of the stallion. The practice of saving the best colt foal of the season from an ordinary mare and using him as a sire for a few years cannot be too strongly condemned. It will result in the breeding of a weedy class of horses, that may be very useful on the farm, but not nearly so profitable from a breeder's point of view. It will be far better to sell the colt, add more money, and obtain a sire carrying a pedigree. The sire to be used should have a small head set on a strong neck, a short strong back, deep shoulders, wide chest, and showing plenty of muscle; hind quarters to match, be well ribbed up, and have a good breech. The body should be carried on legs of medium length, showing good bone and plenty of fine hair. When standing at ease there should be a slight lean forward, indicating a willingness to go into the collar. As I am limiting the price that the average farmer gives for a stallion at around 50 guineas, it is hardly likely that perfection will be obtained. Of course, if the farmer can afford to give 100, or even 200 guineas, for a sire, so much the better for the man and the stock he will breed. If there is any fault in the horse let it be in the hind quarters rather than in the fore quarters, or in the body rather than in the legs. One can put on a top, but one cannot improve the legs. At the same time, avoid an ill-proportioned horse. The stallion should be good tempered and a good free worker. Be shy of a horse that is too closely knit together; he is likely to lack spirit and movement, qualities so essential to a good farm horse. Have nothing to do with an animal that is not thoroughly sound. *The Mare.*—Regarding the mares for breeding, much need not be said. It is always wise, however, to get the best the farmer's financial position will allow. My principle has been to work with the best material I have on hand, always bearing in mind the better the quality of the mare used the better will be the quality of the stock. It is very unsatisfactory in breeding from mares that are not sound, and also good workers. Be sure that if one breeds from a "jib" a "jib" will result as a general rule. The care of the mare at the time of foaling is a very important matter. If she is a steady worker she may be kept at work up to the day of foaling. During our first year in this district we had five foals. Each mare did her share of scrub-rolling and heavy carting over heavy ungrubbed tracks without detriment, working right up to date of foaling. In fact, I am inclined to think that if the mare is spelling for five or six weeks on good feed before foaling, one may expect trouble. She will become too fat. When the mare indicates that her time is nearly due, she should be kept in a convenient paddock or yard, where she can be observed frequently. At the time of foaling a little help from an attendant will often save a lot of wasted energy and strength on the part of the mare and the foal, and very often save the life of both. The attendant should also be provided with a pocketknife and piece of string, for sometimes the navel-cord needs tying and severing. If the weather is very frosty when the foal arrives it will be well to put the mare and foal in a shed or some place of safety. If there is not such a place available, then a small warm rug should be made and tied on the foal for the first night or two. One heavy frost may do irreparable damage to a new-born foal. After the mare has foaled she should not be put to work for at least three weeks. In fact, it is better to allow her to have as long a spell as possible, so that the whole of her attention may be spent on feeding her offspring. When the mare is put to work while feeding the foal she should be given plenty of succulent fodder, and the youngster should not be allowed to travel after her; travelling long distances day after day is apt to do harm to its legs.

*Weaning the Foal.*—When about six months old, the foal may be weaned by being shut away from its mother, and having plenty of water and all it can eat of good, nutritious food, in which bran forms a large part. After it is weaned it may be fed on the same feed as the working horses. If there is room in

the stable they may be allowed to feed with their mothers. The young stock should be kept growing. A foal or a yearling that is allowed to become stunted takes a long time to recover, and usually develops abnormal growth of one part. Nor will the animal be so well able to resist disease of any form by which it may happen to be attacked. Of course, it is all very well to say keep the young stock growing when there is plenty of feed in the paddocks or fodder in the yards, but in a season like the present it becomes somewhat of a problem on many farms, where the difficulty is to procure fodder for the workers. I do not think surplus stock, especially horses, should be kept on any farm where no effort is made to store up a supply of cheap fodder for use in a time of drought like the present. If there are only two or three young horses on a farm let them have the same treatment as the workers, because their feed will not be missed. But where the number of yearlings and two-year-olds runs into eight or a dozen, it becomes a matter of expense that will probably absorb the profit of keeping them. For the last four or five months we have fed eight colts and fillies rising two years old on caveings sifted out of the cocky chaff that has been used for feeding the workers, and on pea straw and cocky chaff. This has been all put into a manger together, and readily eaten without anything else mixed with it. Thus fed by day, and with the little picking they could get in the paddock where they are turned at night, has kept them in fair condition. Since, however, the heavy frost has cut back the green picking to vanishing point, it has been found necessary to add a little oats to the daily feed. Taken on the whole, it has been cheap feeding, and when the green feed comes, the horses will be in a condition to make the most of it. If there had not been cocky chaff available, the only alternative would have been to have fed them on hay chaff, and the hay chaff would have been so "tasty" that they would have had no appetite for the picking in the paddock. In conclusion, I am not advocating the breeding of horses as a grazing proposition purely and simply, because one cannot surpass sheep in that respect; but on every well-arranged farm a fair number of young horses can be reared to replace losses, to add to the size of the teams when required, or to place on the market when not required on the farm." Members discussed the paper at considerable length. Mr. D. McCormack thought jibbing was not hereditary, but was due to careless driving. He mentioned the stamp of horse which he preferred. The hon. secretary (Mr. J. McCormack) endorsed the remarks of the writer of the paper in relation to the wisdom of breeding at present.

#### CLAYPAN BORE (Average annual rainfall, 16in. to 17in.).

August 31st.—Present: 10 members.

HAY.—Mr. E. Cobmill read an interesting paper. He considered that every farmer should endeavour to cut and stack 5 tons of hay per year for each working horse. This would ensure a surplus. In dry seasons he would sow Gluyas very early at the rate of 1½ bush. of seed with about 90 lbs. super. to the acre. For wet years he preferred Marshall's No. 3 or White Tuscan. Long narrow stooks enabled the hay to dry well. The stacks should be built on solid foundations of wood or straw. If the stack were to stand for twelve months or so he would strongly recommend the addition of salt to the hay when stacking; this would keep it green and generally improve it. He deprecated the practice of building stacks close to the stable, as this increased the danger of fire. The writer mentioned the value of Algerian oats for grazing purposes or for feed in the sheaf. It was a very economical fodder for fattening stock for market. Oaten hay could be cut whilst green so long as it had developed a good kernel of grain. It would deteriorate if left exposed to the sun too long before stacking. If the crop of oats were large, portion could be cut for hay and the remainder reaped. The straw left after reaping could be cut and then chaffed—to be fed to stock during slack times. Members discussed the paper, and generally agreed with the writer. Mr. Robinson did not favor cutting oaten straw after reaping; he preferred wheat straw. Mr. D. McCormack recommended cutting all the oat crop and putting it through the header. By this means there would be no waste of oats. The chairman (Mr. G. Gray) agreed.

#### COONALPYN (Average annual rainfall, 17.49in.).

October 2nd.—Present: eight members and three visitors.

CULTIVATION OF FALLOW.—This subject was dealt with in a paper by Mr. J. J. Cronin. After the first ploughing, the land should be left for a month or so to the influence of the weather, and to enable any turned in vegetable matter to decay,

he said. Subsequently, after each rain, right up to seeding time, it should be worked, and before seeding it should be skim-ploughed to a depth of 2in. or 2½in. All stumps, large stones, &c., should be cleared off after the first harrowing.

**HAYMAKING.**—Mr. W. G. Collier then read a paper on this subject. Wheatens hay, he said, should be cut about a fortnight after the flower had formed, provided it could be cut in a week. At this stage the hay was at its heaviest. Oaten hay should be cut when almost ripe, for if cut before, it would be found very bitter. Stooking should be commenced very soon after binding. If cut a little on the green side, the sheaves could be left for a day or so; 20 or 30 middle-sized sheaves should go to one stook. When stacking care should be taken that only thoroughly dry sheaves were placed in the stack, which should be built on hard ground, and have a trench dug round to carry off any water which might collect. Straw, for preference, or logs, stones, roots, &c., should first be put down as a foundation. He preferred round-ended stacks. The writer then described his method of stack-building. Members then discussed both papers.

#### LONG FLAT.

September 28th.—Present: 15 members.

**GRAZING COWS.**—In a short paper on this subject Mr. E. T. Forster informed members that he had been feeding lucerne to 10 or 12 cows for two years past, at times for three months continuously, without any of the animals being troubled with bloat. His method was to see that the cows had a good feed of oats or barley before being turned on the lucerne, which should be done after sun-down. While grazing on the lucerne the animals should have free access to water. He had not found them more susceptible to bloating while heavy in calf, nor had he noticed any one cow more liable to this trouble than another. In the discussion which followed Mr. Squire stated that he had left cows on the lucerne from 20 minutes to half an hour three times per day, with no ill effects. Mr. Opie advised giving the animals a good feed of hay before turning them on to lucerne. Cows on a very short growth of this fodder, he had noticed suffering from bloat. Mr. Liebelt had cured bloating by placing one end of a piece of ½-in. hose x 3ft. long, previously dipped in Stockholm tar, down the throat of the affected animal, and Mr. Prouse had obtained good results by placing a teaspoonful of boric acid on the animal's tongue.

#### MANTUNG.

September 12th.—Present: six members and one visitor.

**FARM SHEDS.**—A short paper on this subject was read by Mr. A. H. Stewart. He preferred a straw-roofed shed for horses, the ends and western side being enclosed with stone, and 6in. or 7in. between the top of the wall and the roof being left for ventilation. The stalls should be 6ft. x 10ft., and two rails should be placed between each horse. The water trough was best in the stable yard, so that the animals could drink when they felt so inclined. The barn should be situated at least three chains from the stable, and he gave the dimensions for this structure, which he thought should have an iron roof and a concrete floor. A lean-to at the back could be satisfactorily utilised for storing implements. Members discussed the paper at length.

**MONARTO SOUTH** (Average annual rainfall, 14in. to 15in.).

October 3rd.—Present: 20 members and five visitors.

**FARM HORSES.**—Mr. Braendler read a paper on this subject. When breeding from draught or medium draught mares, he recommended the use of a Clydesdale stallion, which had the Government certificate for soundness. The foals should be kept in good condition until they were broken, and between the ages of two and a half years and four years should receive light work only. The animals should be watered before being fed. Generally feeding was done at too long intervals for the good of the animals. Considerable care was necessary when the feed of the horses was being changed. The majority of members agreed with the ideas expressed in the paper.

**PARILLA** (Average annual rainfall, 16in. to 17in.).

October 1st.—Present: 14 members and two visitors.

**FENCING.**—Mr. C. S. Foale read a paper dealing with this subject. The erection of a sheep-proof fence would be an expensive undertaking, he said. He advised members to utilise posts bored for six wires, but only the number of wires that

were necessary for the time, and then complete the fence as they could meet the necessary expenditure. If posts were plentiful he would put them in half a chain apart, with two iron standards between, but if they were expensive, one to the chain, with five iron standards in between could be made to serve the purpose. Another suitable fence could be erected where posts were scarce by placing strainers eight chains apart intersected by one post. Six iron standards to the chain would be required for this fence. Strainers could be bought for £5 per 100 on trucks Parilla, and this quantity would be sufficient for 10 miles of fencing. The materials required for any of the fences mentioned would cost about £20 per mile, but if the posts could be obtained on the holding, of course, the cost would be considerably reduced. He did not favor using wirenetting for sheep-proof fences on account of the expense, but where rabbits were troublesome the wirenetting was very necessary. He had found that iron standards lasted for very many years, and became very firm in the earth. The angle standards were best, and these could be obtained with holes spaced as required. He preferred to have the top two wires 12in. apart, and the remainder 6in. apart. The paper was discussed at considerable length. Members generally favored gum posts, but while some preferred the wirenetting fence, others thought it a failure in sandy districts on account of drift. Different ideas as to the best distance apart to have the posts, and of the spacing of the wires were expressed by several of those present.

#### RENMARK (Average annual rainfall, 10.93in.).

August 6th.—Present: 13 members.

CROSS-FERTILISATION OF PEARS.—The chairman (Mr. F. H. Basey) delivered an address on this subject. He mentioned that the two chief means of exchange of pollen between different trees and plants were flying insects (particularly bees) and wind. The consensus of opinion had always favored the insects as the greater inter-changers of pollen. Some interesting experiments recently conducted to ascertain the influence of wind as a carrier seemed to indicate that this was almost a negligible factor. Plates of glass smeared with a sticky substance were exposed at various heights on poles adjacent to trees in bloom, and afterwards subjected to examination under a microscope, and very few grains of pollen were caught on the glass, although a strong wind was blowing during the test. His own experience last season, however, in the pear orchard upset his faith in the bee a good deal. The orchard consisted in the greater part of Williams's Bon Chretien, with a grove of Glou Moreceau planted approximately in the centre thereof. During the blossoming season the varieties flowered together, and the orchard was alive with bees from an apiary situated nearby. There was every ground for supposing that they operated with equal industry over the whole area, and therefore cross-fertilisation would be fully effected between the whole of the trees of the orchard. When the pears had set, however, it was noticed that two rows of Williams' Bon Chretien on each side of the Glou Moreceaus, and two rows of the latter alongside of the former were carrying far away heavier crops than the rest. From this it would appear that the wind was, after all, the main factor in carrying pollen. He had planned out his plantings of pear trees this year in accordance with this theory, planting the rows north and south to allow the prevalent west wind full play in carrying the fertilising pollen. Last year, when planting a small area with prunes, he went to a good deal of trouble to ascertain the flowering dates of various varieties, but was quite unable to get any information on the matter. He suggested that the careful collection, tabulation, and annual publication of the blossoming periods of all the fruit trees in the various experimental orchards was a course to be highly commended. He had taken careful note of the dates of blossoming last season. He intended following this practice each year, and urged members to do likewise. A comparison of observation could be made at, say, the October meeting of the Branch, and carefully tabulated; this information should prove of great value. Mr. Basey exhibited a list showing the date of the first bloom, date of full bloom, the date of last bloom of a number of varieties of almonds, plums, nectarines, peaches, apricots, pears, and apples. [As the added experience of future years is accumulated, this will provide reliable data for the guidance of growers; as the experience of a single year cannot be accepted as conclusive, the list is not published, but copy of same may be had on application to the Department of Agriculture. The Horticultural Instructor states that the dates of blooming, &c., are being fully recorded

at the Government Orchard, at Blackwood. These have not been published for the reason that it is desired to be in a position to give the results of a succession of years before launching any statements for the acceptance of intending planters.—ED.]

**WILKAWATT** (Average annual rainfall, 16in. to 17in.).

September 29th.—Present: 15 members and one visitor.

**CLEANING WHEAT.**—A short paper on this subject was read by Mr. E. Altus. He emphasized the necessity of keeping the sieves of the machine clean, and turning the machine regularly. He thought the screenings should be bagged from under the machine in preference to putting them back in the heap. Members discussed the paper.

**CLAYPAN BORE.**—The chairman (Mr. J. Gray) reported having visited the western districts of Victoria in search of summer feed for stock. Conditions there were no more satisfactory than those at Pinnaroo. Dry feed was reported to be available at Pine Plains.

**HALIDON, September 23rd.—IRRIGATION.**—In discussing the paper read at the annual congress by Mr. McIntosh (Director of Irrigation), Mr. Clark drew attention to the remarks that bore water would probably need aeration for a day or so before being applied to plant life. The effect of carbonate of soda in local bore water could be nullified by applying gypsum to the soil. Mr. Weste stated that at Benmark it was necessary to apply gypsum to the soil when irrigating from the Murray River. Mr. Gallasch considered that a better pressure could be obtained from the storage tanks by making the outlet in the centre of the bottom of the tank, and having the outlet larger than the mains intended to be used. Members agreed that it was beneficial to mulch plots to be watered.

**KINGSTON-ON-MURRAY, October 3rd.**—Mr. S. Sanders gave a demonstration of budding and grafting. He advised budding deciduous trees on their own roots. Buds intended to lie dormant should be put in as late as possible in this district, March not being too late. Buds should be taken from well-ripened wood, avoiding each end of the shoot. In grafting, the main essential was to have the stocks in a forward state, and the scions in check. The scions should be taken off trees pruned on the late side, and packed away in a cool place in dry sand.

**PARRAKIE, August 8th.—LOCAL VETERINARY SERVICES.**—Mr. Diener initiated a discussion on the advisableness of having a veterinary surgeon resident in the district. Farmers, he said, often lost stock that would have been saved if a veterinary surgeon had been within handy distance. He suggested measures to meet the necessary cost of keeping a competent man in the district. Mr. Beddome agreed, and thought that farmers in the district would greatly benefit by such a scheme.

## SOUTH AND HILLS DISTRICT.

**BLACKWOOD** (Average annual rainfall, 27in. to 29in.).

September 21st.—Present: 21 members.

**GARDEN IMPLEMENTS.**—In opening the discussion on this subject, Mr. P. H. Williams said that he favored the Green Mountain gooseneck hoe for general use; and thought the best tine hoe was made by bending the paddock fork over and fixing it to a handle. Where hard ground had to be broken up or for cleaning footpaths, the mattock was useful; but for chopping out briars and bushes the grubbing axe was best. For working under trees the two-pronged hoe, prongs  $1\frac{1}{4}$ in. wide and 2in. apart, was preferred. The single-horse Planet Junior cultivator was a good all-round implement—it was more easily controlled and could be worked nearer the trees than the two-horse cultivator. The spring-tooth harrow was also very useful. Mr. James stated that three-pronged hoes were the best for hoeing around trees. He also favored the spring-tooth harrow, provided the soil had been well ploughed. Mr. Gamble preferred the gooseneck hoe for strawberry beds, and the square-pronged hoe for working around trees. Mr. Penno used the square-pronged fork—bent—for ordinary use, and the double-pointed pick for hard ground. The Planet Junior two-horse cultivator gave him better results on the hillside than the single-

horse. Mr. Winser had fixed discs on his two-horse cultivator, but the result had not been satisfactory. Mr. Magarey reported that he was using a disc harrow on land that was too hard to plough, and by going over it twice or three times had worked the soil to a depth of 4in. He found it would work in land that was too hard for the ordinary cultivator, the only objection being that the harrow was inclined to leave ridges. The hon. secretary (Mr. C. G. Savage) stated that the spring-tooth cultivator was giving better results than the fixed one, and that a new orchard plough, with the long bridle and moveable handles, was giving good results.

#### CHERRY GARDENS (Average annual rainfall, 35.03in.).

September 1st.—Present: 14 members and one visitor.

APPLE EXPORT TRADE.—In reviewing last season's export trade in apples Mr. S. W. Chapman mentioned in a paper that although the apple crops were heavy, the exports had been small on account of *fusicladium*, and of the quantity of small, un-matured fruit. Fruit sold up to the end of May realised good prices, but that disposed of after that date met a falling market. Australian apples, he said, should reach the home markets in April and May. He then gave figures showing the results of a few of last year's shipments, and the agents' reports on the fruit. From these it would be seen that there was great need to enforce regulations to prevent the export of small, immature fruit, that late shipments were a failure, and that the Rome Beauty was too late in ripening to be suitable for export. He advised storing this variety for the local market. Previous shipments had shown that the three-tray case was the best for exporting pears. He favored the establishment of co-operative packing sheds, which already existed at Forest Range and Angaston. Mr. C. Bicks agreed that it was unwise to ship immature fruit, or fruit of unsuitable varieties. Mr. T. Jacobs advised members to keep the Rome Beauty for the local trade only.

HAY AND PEA CROPS.—Various members commented on the splendid appearance of these crops in this district, especially those on well cultivated and manured fields.

#### CLARENDON (Average annual rainfall, 33.67in.).

August 31st.—Present: 17 members and two visitors.

HORSE BREEDING.—Three short papers were read on this subject. Mr. A. A. Harper preferred the Clydesdale for this district. He bred from young stock. The mare should be well built, have good bone and muscle, short joints, deep quarters, a short, tapered neck, small head, be good tempered and be well ribbed up. It was important to see that the stallion had good feet. He should be upstanding, clean-legged, have good bone and muscle, deep quarters, and round barrel and a good temper. Both before and after foaling the mare should be well fed and attended to. It was important to keep the foal growing. If feed became scarce, oaten hay should be given, as this was a good bone and muscle builder.

Mr. J. Piggot, in a paper on light stock recommended mating a mare of good bone and constitution to a pure-bred stallion, which should have good legs, feet, and temper. He preferred the Arab breed, as they were hardy and good travellers. Thorough-bred stock were too light in the bone and were unsuitable for the hard roads. He considered the light stock bred in the north the best, as they grew a better hoof than those bred on hilly country, whose feet were long and narrow.

Mr. H. C. Harper recommended two classes of farm horse—the Suffolk Punch, and stock from a draught mare by a light thoroughbred stallion. He preferred the light stallion because the progeny would then be clean-legged, and also have good bone, muscle, and pace. A lengthy discussion followed the reading of these papers, in which Mr. J. Spencer mentioned that many of the sires now used were too fat, and this reduced the stamina of their offspring. Mr. A. Harper had proved the Suffolk Punch very reliable, but was opposed to the pure-blooded stallion, as it was unsatisfactory for heavy pulling. The Hon. Secretary (Mr. L. B. Brooks) considered the draught mare mated with a roadster stallion of good bone produced good stock, that had good pace as well as draught power.

#### HARTLEY (Average annual rainfall, 15in. to 16in.).

September 2nd.—Present: 18 members.

CONSERVING FODDER FOR STOCK.—Under this heading a paper was read by Mr. H. Cross. Cocky chaff, mixed with crushed oats or bran and molasses,

would provide good stock feed, he said. Straw could also be stacked in each paddock on the farm. Oaten straw cut and chaffed immediately after the harvester had been through it made good feed. Crushed oats, mixed with chaff, were better than bran, as a cream producer, and far more could be obtained for the oats in this way than by selling them for 1s. 3d. to 1s. 6d., the prices realised this year. It would pay farmers handsomely to prepare a few acres of fallow each year, and put in barley, rye, or oats, when the early rains came in March or beginning of April. This would be in readiness for the stock in a month, and would keep them in good heart until sufficient feed was in the paddocks. For the summer months such fodders as lucerne, mangolds, kale, and chou moellier could be put in with advantage. Field peas were also a good fodder.

#### KANMANTOO (Average annual rainfall, 17.90in.).

August 29th.—Present: eight members and three visitors.

**EXPERIMENTAL PLOTS.**—Mr. E. W. Shepherd reported on experimental plots sown by Mr. W. C. Mills. Whilst Buddo, Yandilla King, Dart's Imperial, and White Gamma varieties of wheat were doing well, Federation looked poorly, and was turning yellow. Crossbred 53, although it stood exceptionally well, was showing the effects of dry weather.

**ROBBERS AND WASTERS ON THE FARM.**—A lengthy paper under this heading was read by Mr. R. W. Downing. By systematic grading of seed, he said, the wheat yield would be increased. The waste involved in drilling in cracked and shrivelled wheat was more than the cost of grading. Only the best stock, poultry, &c., should be kept. Good fowls would be found very profitable, especially in times of drought. Much was lost by the man who neglected his implements and machinery. He considered sheep tick one of the greatest robbers to be contended with. Rabbits, noxious weeds, and other such pests all reduced the farmer's income.

#### LONGWOOD (Average annual rainfall, 37in. to 38in.).

September 5th.—Present: nine members and three visitors.

The meeting was held at the homestead of Mr. E. W. Beythein. Members inspected the poultry plant, and were particularly interested in the incubators. Mr. Beythein explained that when turning the eggs it was wise to turn the trays end for end. He used the hot-air machines, which were found to be most suitable to the moist atmosphere of the hills districts. Hatching was completed by the 22nd August. When hatched the chickens were transferred to the brooders, each of which had a number of yards attached; chicks of equal age and size being placed together in each yard. For the first month they were fed principally on broken wheat. The yards for the breeders and laying hens faced the east, and were so arranged that the attendant could go through from one to the other. Those recently erected had scratching pens. Mr. Beythein gave some useful hints on feeding, cleaning, and general management. To prevent egg-eating he had found placing china eggs about the yard effective. An irrigating plant for growing greenfeed was inspected. The greenfeed was passed through the chaffcutter before being fed to the poultry.

#### MEADOWS (Average annual rainfall, 35.52in.).

September 1st.—Present: 15 members.

**CULTIVATION OF MANGOLDS.**—Dealing with this subject in a paper, Mr. W. Nicolle said that practically any class of soil in a district of good rainfall would grow a fair crop of mangolds, providing heavy manuring was practised. Better crops, however, could be secured from land that was naturally moist through the summer, if it were of a deep, loamy nature over a good clay subsoil. If irrigation could be carried out, of course, the returns would be still further enhanced. The most suitable fertiliser was pig manure, and next to this stable manure. This should be allowed to thoroughly rot in pits, and then applied in heavy dressings to the land in autumn, be ploughed in, and then harrowed. A crop of white oats for green feed could precede the mangold crop, in which case the oats should be got rid of before the middle of July, and the land ploughed and harrowed again. About the middle of August the land should be again ploughed to a depth of 9in., and scarified and harrowed, and rolled until it was reduced to a fine tilth. About 2cwt. of salt to the acre should then be applied to the land, and worked in. The variety of mangolds he preferred was Mammoth Long Red. The Globe variety

was a slower grower when young, and was not so likely to produce such a good plant. The seed could either be sown through the drill, or by hand, in rows 24in. or 27in. apart, to give room for working a horse between the rows. A few seed should be dropped together into the drills, at each space of about 12in. A harrows and light roller should then be put over the land, care being taken to keep the horse between the rows. The horse-hoe should be used as soon as the rows were visible. The hoe should be put over frequently to keep it free of weeds. When large enough the outside leaves could be stripped, and used for stock feed. This could be done several times in the year. The roots made excellent feed for cattle, pigs, sheep, and poultry. For feeding to cows they should be sliced; for pigs or sheep they could be fed whole or sliced. If boiled for pig feed, they should be sliced, and if for cows, a little pollard should be added. This made excellent food for store pigs or sows. The chairman (Mr. Geo. Ellis) said mangolds constituted the best crops for feeding to sheep and pigs that could be grown in this district. Mr. Smith stated that he sowed mangold seed in September last year. The plants were destroyed by slugs and sorrel; however, so he resowed the ground in November and December. A good crop, with some of the roots weighing up to 19lbs. each, resulted. Mr. Morris thought a good supply of leaves would be secured by early planting.

QUESTIONS.—Members considered the best long hay for horses was wheaten; for chaffing, they preferred mixed oats and wheat. On good land, in a normal season, about the first week in August was the best time to sow field peas; the peas then made less straw than if planted earlier.

#### MOUNT BARKER (Average annual rainfall, 30.93in.).

September 2nd.—Present: nine members.

ORIGIN OF SOILS.—An interesting paper dealing with this subject was read by Mr. B. Fidler. He mentioned that it was essential for the farmer, in order to treat his surface soil rationally, to have a clear idea of the formation of it. Many interesting geological facts were mentioned and explained, and the physical effects of the weather, &c., on rocks were dealt with.

---

#### MYPONGA.

July 8th.—Present: 10 members.

LAMB-RAISING.—This subject was dealt with in a paper by Mr. A. Sinclair. The Merino-Lincoln cross, he said, was admirably suited to the country north of Petersburg. The South Down, crossed with the Lincoln-Merino ewe, produced well-shaped lambs, of very fine quality, but being slow maturers, they were not favored by small holders for export purposes. Most small holders in the south preferred the Shropshire, which, if crossed with the Lincoln-Merino ewe, produced a nice-shaped lamb, which matured fairly early. He recommended any small holder who wished to breed lambs for export to mate a Dorset Horn ram with the Lincoln-Merino cross ewe. The Leicester mated with the Lincoln-Merino cross produced a splendid lamb, of good shape and very hardy, and a good butcher's sheep. This cross would do well in the Middle and Lower North and also in the South-East. Another breed he favored for the Southern and South-Eastern districts was the Romney Marsh. This breed, crossed with the Lincoln or Shropshire, produced a good export or market lamb. Paddocks should be reserved for the ewes during lambing season. These paddocks should be subdivided, so that the ewes and lambs could be occasionally placed on fresh feed. Peas were good for fattening lambs, but in the event of summer rains the peas would have to be fed off quickly, otherwise they would shoot, and lose their value as a fattening fodder. He therefore recommended sowing barley, oats, rape, mustard, or cow-grass clover, which would ensure plenty of fodder. In discussing the paper the chairman (Mr. G. Hunt) stated that he had a high percentage of lambs, which he attributed to the good condition of the breeding ewes at the mating season. Members generally considered that the reason for mating an English breed of ram with the Merino ewe, instead of a Merino ram with an English breed of ewes, was that it would be difficult to procure a flock of ewes of good mutton quality, and also that the sire had the greater influence on the offspring.

**IRONBANK, August 29th.**—Mr. R. Coats recommended kerosene emulsion or liquid sulphur as an effective spray for the red spider. For spraying apple and pear trees he favored Bordeaux, or a mixture of 5lbs. bluestone and 7lbs. washing soda to 50galls. of water. For gumming on Japanese plums the hon. secretary (Mr. W. Coats) recommended nipping the trees as much as possible during August or a little earlier with equal quantities of clay and fresh cowdung, mixed to the consistency of porridge.

## SOUTH-EAST DISTRICT.

**KYBYBOLITE** (Average annual rainfall, 22in.).

September 3rd.—Present: 10 members.

**FENCING.**—A short paper on this subject was read by the chairman (Mr. A. Bradley), who recommended fences built to the following specifications:—Boundary fence—Posts 3ft. 6in. out of ground, 20in. to 22in. in ground, 33ft. apart, with two droppers in between, suspended clear of the ground; five plain wires, and a barbed wire on top, placed as follows:—Bottom wire 6in. from ground, second 12in., third 18in., fourth 25in., and fifth 33in., and sixth 42in. from ground. Division Fence—Posts 3ft. 4in. with four plain wires, and barb on top, placed as follows:—Bottom wire 7in. from ground, second 14in., third 21in., fourth 30in., and fifth 40in. from ground; posts 33ft. apart, with two droppers between. The best wire to use was hard steel 12½ gauge galvanized, the breaking strain of which was equal to that of the ordinary No. 8 black wire. Red gum posts cost anything from £2 to £5 per 100. He thought the saving in both material and labor was very considerable in this class of fence.

**LUCINDALE** (Annual average rainfall, 23.32in.).

October.—Present: six members.

**FODDER CROPS.**—Mr. W. Secker read a paper on this subject. The principal varieties of fodder crops grown in this district, he said, were rape and kale. The paper continued:—Rape is one of the best, if not the most popular of root crops. Its fattening properties are far ahead of kale or mangolds. It is to be highly recommended as a catch crop on fallow ground, as it is quick maturing, and may be fed off, sometimes twice, before working and sowing the fallow with grain. There are three varieties of kale, namely, Jersey tree, thousand-headed, chou moullier or Guernsey marrow kale. The first-mentioned variety is not grown in these parts, consequently we are not likely to get any local information about it. The thousand-headed kale is the best known. It does not mature so quickly as rape, but by judicious feeding many crops may be got from the one sowing. One objection is that it has a large root system; the old stumps get a good grip, and the plough does not turn them all out. For the past four years we have grown about an acre of chou moullier each year for the milch cows. We usually start pulling it about December, and keep at it right up to the end of April; we then let it go up to seed in the following summer. Last year we gathered over 2cwt. of seed from an acre. The method that we adopted to gather the seed was to spread a tarpaulin in a spring cart, cut off the seed heads, and cart them into a shed, where we threshed the seed out by forking and knocking it about. The seed falls through to the bottom; the waste stalks can be forked off and thrown out; and the remainder winnowed. Some of the Naracoorte farmers sowed this variety of kale through the wheat that they intended to strip, and I heard that it did very well. They thus secured an excellent sheep feed through their stubble. We have adopted this method with 45 acres of wheat and about 20 acres of oats. I broadcasted the seed on the wheat after it had germinated, and left the kale seed to be covered by the rains. When I sowed the oats I mixed the kale seed with it, and it resulted in an even sowing. This looks better than that which was broadcasted. Peas are extensively grown by many of the fat-lamb raisers, and it is always noticeable in the Adelaide saleyards that the best lambs are pea fattened. Mustard does not take long to grow. In from six to eight weeks it is fit to feed off. Our only experience with this crop was an area of about 6 acres. We sowed it in the autumn, and in about seven weeks it was about 2½ft. high, just flowering, when we turned some ewes on to it. At

first they did not take to it well, but after a few days they ate it, and it was not long before they cleared it right out. These sheep looked better right through the winter than any others of our flock. August and September are the usual times for sowing root crops, but mustard is best sown in the autumn. Some also sow rape in the autumn, but I do not think it would do with us, as our average winters are too cold to keep it growing when the cold weather comes on. There are three methods of sowing small seeds, such as kale, rape, turnips, and mustard. Personally, I prefer the Cahoon seedsower for broadcasting. By cutting out a new slide with only a small V in the bottom of it, quantities may be sown down to as low as  $\frac{1}{2}$  lb. to the acre. Another method is to mix the seed with the corn through the drill—that is, if it is desired to have kale through the stubble after stripping. Kale does not make great growth, and does not interfere with stripping. The other method is to mix the seed with the superphosphates, but great care must be taken only to mix sufficient seed just to keep going, because the super, when mixed for any time with the seed, lessens the germinating powers. It is well worth while testing the seed, say ten days before it is intended to sow. All that is needed is a little absorbent cotton, or wadding, as it is commonly called, and a saucer; place the wadding in the saucer, and moisten it with water. Then count 100 seeds on to it, and place it in a shady place and keep it moist. As the seeds germinate throw them out of the saucer. The seeds that do not germinate are consequently left to the last. Count these, and it will give the percentage of the seed which is not good." Mr. Beaton had sown 160 acres of rape and  $4\frac{1}{2}$  acres of peas this year, but the season was too dry for the best results to be secured from these crops. Mr. McMorrow mentioned the Elephant swede as being a good fodder for dry seasons; this plant drew its moisture from a greater depth than most fodders.

#### NARACOORTE (Average annual rainfall, 22.60in.).

September 19th.—Present: 16 members and two visitors.

**PEAGROWING.**—Mr. S. H. Schinckel read the following paper:—"Peagrowing in the South East will receive much more attention when the full value of this plant as a forage crop and a soil renovator is better understood by farmers. Peas may be grown on various soils. Loamy soil generally gives best results, provided there is a good drainage. They will also grow on our poor, sandy soil with a liberal application of manures, if there is a good rainfall, especially after the flowering stage. The variety most favored is the Dun. This should be sown at the rate of about 2 bush. per acre. The best manures to use in a wet district are bonedust or bone super., at the rate of about 1 cwt. per acre; a little less might be used for heavy soils. The seed should be put in to a depth of from 2 in. to 3 in., about the end of June or early in July, on well-prepared land. If sown too early there is always the danger of the crop, when in bloom, being cut with the later frost. On the other hand, if sown too late, there is always the danger of the pea being cut with hot winds. The method of harvesting most favored in the Hills district is with the ordinary mower, with an attachment. The attachment, or buncher, consists of a false set of fingers, about 2 ft. long, fixed on to the fingers of the mower, and places the pea haulms in a straight position for the knife, after which they fall back in a sort of cradle. The attendant following the machine rolls them a few times with a fork, and when in a nice handy size for handling, pushes them off out of the way of the horses for the next round. Peas can also be harvested with the ordinary horse rake, which rakes them into rows. If it is intended to have a clean raking they should be raked the second time, by driving the rake the opposite way between the rows. When raking is completed, the peas should be put into convenient-sized heaps. It is best to do the work early in the day, in order to prevent shelling. If the weather is cool, however, the rake may be used any time of the day. Whichever method is adopted for harvesting, it should be done before the peas are too ripe. Stacking is best done early in the day, to minimise shaking. I fail to see the advantage of trying to make a high stack, for the less the peas are handled the less they will shake. When finishing the stack it should be kept fairly full in the centre, and covered with straw at the earliest convenience, to prevent damage by rain. Threshing is best done by the average farmer with a land roller. The peas should be put in a circle on a fairly hard and even piece of ground, and the roller driven round a few times; an assistant should then turn the peas

with a fork. A few more rounds with the roller, and then the peas can be caved, and the haulms put out of the way, and the circle is ready for the next lot of peas to be rolled. There is no necessity to clean up the peas after each rolling. When rolling is completed they are put through the winnower in the ordinary way. If only a small quantity is to be threshed, I prefer not to stack them, but to cart direct to the threshing ring, roll as before stated, and put all haulms in the centre of the ring. It will be found that this saves a great deal of labor. Some may think that by threshing peas on the ground by rolling a lot of waste would result. Such, however, is not the case, as pigs or sheep will pick up almost every pea left. As a fodder I doubt if any crop that we can grow will give better results for fattening pigs. They are also very useful for fattening sheep or lambs. Sheep and lambs may be put direct into the field when the peas are just on the turn. The sheep eat a lot of the green haulms, and gradually take to the peas, which they devour greedily, and fatten very rapidly. Grass, or some other variety of food, and a good supply of water, should be available. If it is intended to feed them to sheep from the stack the peas should be carted out into the grazing paddock, as required. This is the method generally adopted by the growers in the Hills district, and seems to give best results. The latter method has an advantage, because when the crop is fed in the paddock, as soon as the peas are done a farmer has to market his sheep. Stacking and carting out enables the sheep to be held until the market for fats is higher. If purchasing sheep or lambs to be fattened on peas, it will be found that it always pays best to buy them in good store condition. Poor sheep or lambs take too long to build up to prime quality. In the matter of soil renovation, it should be remembered that peas possess the power of absorbing the free nitrogen of the air by means of the nodules on their roots, and are, therefore, able to thrive without the aid of nitrogen in the soil. However, it must not be forgotten that while a pea crop greatly increases the fertility of the soil, phosphates should not be omitted if a cereal crop is to follow, for without the latter there would be an excess of nitrogen, causing a heavy, rank growth, at the sacrifice of the grain. Grazing peas off the farm by sheep not only means that the revenue of the farmer will be augmented, but the fertility of the soil will be rapidly raised. By feeding off the crop the body of the animal is nourished, and the greater portion of the manurial substances in the feed passes into the manure, so that not only are the fertile elements returned to the soil, but its fertility is further increased by a large supply of humus. Meat is at a high figure, and is likely to be so for many years to come; therefore it is our duty to do all that we can by way of producing fat stock to prevent prohibitive prices for the consumer. The returns secured by feeding peas off by sheep to produce saleable meat, and manuring the land with the droppings, will be found much more profitable than ploughing them under as green manure." Mr. Loller mentioned that peas cut in the green stage made good ensilage, on which stock did well. Mr. W. H. Smith thought it paid better to feed the crop off in the paddock than to harvest it. Harvesting was expensive. A crop of hay on his holding this year, which was on land that last year carried peas, looked better than any other on the farm. Mr. E. S. Alcock endorsed the remarks of the previous speakers.

---

KEITH, September 5th.—In reply to a question by Mr. Shannon, Mr. Brailly stated that barley was unsuitable for hay. The chairman (Mr. Thompson) considered it good feed for cows. Members generally thought that this cereal should be harvested, the straw being then cut and chaffed.

NARACOORTE, August 8th.—Mr. A. Caldwell read a paper on "The Benefits likely to accrue to the Agricultural Industry in the South-East by the Extension of the Broad Gauge Railway System."

## INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

### STOCK INQUIRIES.

(Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"E.J.S.A.," Coonawarra, asks treatment for (1) pony which has puffy fetlocks and contracted feet, causing lameness; (2) for terrier which, after violent exertion, loses power in hindquarters, and has a chronic sore back.

Reply—(1) The excessive dryness of the ground has something to do with the lameness, which will show more if the pony is bare foot, but it will be better without shoes until the feet become tender, when tip shoes will suit. It will be well to dress the feet daily with a mixture of half Stockholm tar and half mutton fat melted together. (2) The symptoms point to gouty eczema, and the diet should be of the lightest. Three pilules of rhus tox, 3x, should be given twice daily. Lotion, tr. rhus tox  $\frac{1}{2}$  oz., water  $\frac{1}{2}$  pint, a little to be applied to the back once daily.

"E.T.W.," Lameroo, asks advice concerning colt, 2 years old, but testicles not in scrotum.

Reply—It is probable that if he is allowed to run with fillies this year that the testicles will be in the scrotum in a few months. If not, there is an operation that a qualified veterinary surgeon who specialises in it could perform, but it would be costly, and as the colt is not a valuable one it would be probably better to destroy him and save his keep.

"J.B.T.," Sutherlands, asks if a foal can be artificially reared.

Reply—A foal can be brought up on the bottle, but it certainly will not pay to do so this season. It should be fed on full cow's milk with a teaspoonful of sugar of milk to each quart. After it is a fortnight old skim milk, boiled linseed, and pea meal may be given, getting gradually up to 2galls. of milk and 4lbs. of mixture per day. As there is a shortage of milk, powdered milk may be used instead with sugar of milk added, but the cost will be prohibitive.

"G.M.W." has horses troubled with bot flies. He asks if it is advisable to spray stable and yards with carbolic solution.

Reply—The flies are more in the open than in stable yards, so it would be better to smear the horses' chins and knees with a mixture such as tar and oil than to incur expense in spraying the stable yards; however, house flies

cause serious worm trouble in horses and breed in dung, so it is a good plan to spray the dung heap once a week with a solution of 1lb. of sulphate of iron to 4galls. of water, stirring the dung at the same time, as the maggots are not on the surface.

"A.W.W.," Parilla, asks treatment for horse suffering from continual scouring.

Reply—Half a pint of castor oil followed by a teaspoonful of sulphate of iron, this latter to be given twice daily in food will probably improve matters in conjunction with lucerne chaff. A teaspoonful of powdered cinnamon once a day will also help.

"W.S.," Middleton, seeks advice concerning mare which went stiff in forelegs after foaling.

Reply—The mare has probably a slight attack of laminitis, which often occurs after foaling. An ounce of Epsom salts in the drinking water three times a day for a few days, and standing the mare in mud or the sea, preferably the latter, for a few hours every day, will probably relieve the trouble.

"P.L.C.," Port Augusta, asks treatment for colt, 2 years, of stunted growth, with yellowish discharge from nose, and harsh cough when excited. His condition is improving on good feed.

Reply—The long continuance of the discharge and the totality of the symptoms point to dental trouble, probably of a scurvy nature, and it is doubtful whether under present circumstances it will be profitable to treat the colt; however, if that is desired, the nostrils should be syringed out once daily for a week with a solution of permanganate of potash, enough to make warm water a delicate pink, and the colt should receive in bran and chaff twice daily for a fortnight a tablespoonful of syrup of phosphate of iron.

"K.G.," Riverton, inquires concerning pony which is losing hair.

Reply—Probably from parasites, combined with overheated blood. Wipe over daily with one part benzine to six or seven parts cheap oil, such as linseed, and give in food twice a day a powder consisting of one flat tablespoonful sulphur, one heaped teaspoonful saltpetre, half a teaspoonful resin. Give for a week.

"H.F.J.H.," Salt Creek, asks treatment for cows with following symptoms—Stiffness in joints, running at nose, diminished milk yield.

Reply—The onset symptoms of so-called dry bible or acute scurvy. As a preventive give all the cows daily a handful of a mixture of sweet bonemeal three parts, saltpetre one part. Treatment—A pint of yeast once or twice daily, 20 drops of tincture bryonia three times daily, and follow after a day or two with syrup of phosphate of iron, two or three tablespoons two or three times a day for a few days. Change food as much as possible, and if it can be managed in any way, give a little green food, even if it is only artichokes or thistles.

"J.H.V.," Brimpton Lake, asks treatment for yearling colt. Near side hind leg is stiff in hock when lifted, and hamstring knots up and leg hangs useless. Symptoms came on after castration.

Reply—Although blood vessels of the leg affected by blood worms would produce somewhat similar symptoms, those described, especially as the colt is fat, point rather to mischief in the stifle, which becomes partially dislocated.

Probably improvement would follow the application of a good sharp blis, such as biniodide of mercury one part, lard seven parts; an ounce would be the quantity required.

"T.S.," Tarlee, lost two cows. Six cows were turned at night into paddock where little Johnson grass; two were found dead in the morning, and another was stiff when walking, and continually lying down. He asks cause of deaths.

Reply—Certain substances called glucosides form in grasses like Johnson grass, and then in the cow's paunch; at certain times further split up into very poisonous compounds which cause bloating and sudden death. It seems possible this has been the case with these cows. As preventive only let them on to the grass with an already full belly. Should accidents arise, a quart of milk or a pound of molasses will generally save those not too far gone, while a stick tied bitwise across the mouth will relieve the urgent bloating symptoms.

#### HORTICULTURE.

A member of the Mount Compass Branch of the Agricultural Bureau inquires *re* thrips in onions.

Mr. George Quinn, Horticultural Instructor, replies—These insects are favored by dry weather, consequently wherever possible the affected plants should be watered overhead by means of sprinklers. Mr. C. French (the Government Entomologist of Victoria) has experimented with various sprays, and found tobacco wash and benzole emulsion the most effective. As benzole emulsion may not be procurable, I suggest a trial be given to either tobacco and soap wash or kerosine emulsion. An emulsion made with benzine (petrol) might be tried, but great care must be exercised in making it, as the boiling soap solution would have to be carried a considerable distance from the fire before adding the petrol.

"P.I.," North Croydon, asks several questions, the nature of which are indicated sufficiently in the replies supplied by Mr. Quinn.

Reply—The reason for the orange trees shedding their leaves each year after flowering is somewhat puzzling, but is most probably attributable to some constitutional defect. Suggest discontinuing use so much stable manure and trying complete fertiliser, such as 2lbs. superphosphate,  $\frac{1}{2}$ lb. sulphate of potash, and  $\frac{1}{2}$ lb. sulphate of ammonia per five-year-old tree. These could be mixed together and applied twice in the year, viz., at early spring time (August or September), and again in Autumn (about March or April). The fertiliser may be sown on the surface, covering an area from just under the boughs to a point a couple of feet outside the spread of foliage of each tree. It may then be dug into and mixed with the soil, preferably with a fork. Another method is to sprinkle the fertiliser into a trench opened around outside the foliage prior to turning the irrigation water into it (2) Kerosine emulsion will assist in repressing the red scale of citrus trees, but not so effectively as fumigation with hydrocyanic acid gas. The latter process, however, is not recommended for the amateur. Kerosine emulsion in small quantities is made as follows:—Take 4 pints kerosine, 2 pints rainwater, 2oz. to 4oz. soap. Slice and dissolve the soap by boiling it in the water, and when the soapsuds are still boiling hot pour in the kerosine. Then with a syringe or force pump lift the mixture from one vessel and propel it with great force into another, backwards and forwards, until the whole mixture thickens into a dense, creamlike mass. This may be diluted as required for spraying on the citrus trees, one part to each 12 parts of fresh water. Trees should not

be sprayed unless the soil is well supplied with moisture at the time. (3) Most of the waters from shallow bores west of the city are heavily charged with injurious salts in so far as citrus trees are concerned. They should be used with caution, avoiding the spread of the water upon the surface of the soil. The water should be run into deep trenches in large soaking doses. As soon as the surfaces of the trenches are no longer sticky they should be broken up, the soil in a loose and dry condition being levelled down again, and where practicable covered with a mulch of manure or litter until the time again arrives for watering. This is ascertained by testing the soil for moisture.

#### ENSILAGE.

"J.W.R.," Morchard asks, "What would be the loss in weight in a green crop of oats, barley, &c., when made into ensilage, or when the ensilage had matured?"

The Director of Agriculture states—The loss in weight in making ensilage depends very largely on the care with which it is handled and made; and also on whether it is stack or pit ensilage that is being considered. Under favorable conditions the loss from fermentation in the pit is about 10 per cent, and one must allow for another 5 per cent. to 10 per cent. for waste and decay; hence in favorable circumstances 5 tons of green stuff should supply about 4 tons of good ensilage. The losses from stack ensilage are always greater, and vary with the size of the stack and the area of its exposed sides.

## PHOSPHATIC MANURES.

### ADDRESS BY THE DIRECTOR OF AGRICULTURE.

At the invitation of the members of the Blyth Branch of the Agricultural Bureau, the Director of Agriculture (Professor Arthur J. Perkins) attended the meeting of that branch held on the 6th November, and addressed the members. The chair was occupied by Mr. A. L. McEwin.

#### PHOSPHATIC MANURES.

The Director took the above as his subject, and said:—In the first instance I would like to point out to you the rapidity with which the use of phosphatic manures has become general in this State. This is a feat of very considerable importance in economics, since it is not easy to persuade a great body of men to adopt what is practically a revolution in practice, simply because one or two have been successful with it. The results tabulated in the following table show that in 1897 the total amount of phosphatic manures used in this State was only 2,000 tons, and the total area of crops treated with that manure only 60,000 acres. If we compare the total area of land under cultivation in 1897 with the area dressed with superphosphate

it will be found that the latter represents only 2.92 per cent. of the former. Reference to the table shows that five years afterwards 24,600 tons of phosphatic manures were used on 500,000 acres; finally, last year, 97,023 tons were applied to 2,659,608 acres, which area represents 85.68 per cent. of the total area put under crop in South Australia in 1913. Within 16 years, therefore, the quantity of manure used has increased 4,851 per cent. The number of acres treated for the same period has increased from 60,000 to 2,659,608. What is perhaps more striking still is that whilst in 1897 the percentage of the area under crop that was manured was 2.92, the figure for 1913 stands at 85.68 per cent. This is, in every sense, a very creditable achievement, and I feel proud at having been connected with an institution which had done a great deal, in the earlier years, to encourage the use of this manure.

TABLE I.—*Showing Steady Increase in Use of Phosphatic Manures in South Australia, 1897-1913.*

| Years.     | Total Quantity<br>of Phosphatic<br>Manures used. | Number of Acres<br>dressed with<br>Phosphatic<br>Manures. | Percentage of<br>Total Area under<br>Crop in South<br>Australia dressed<br>with Phosphatic<br>Manures. |
|------------|--------------------------------------------------|-----------------------------------------------------------|--------------------------------------------------------------------------------------------------------|
|            | Tons.                                            | Acres.                                                    | %                                                                                                      |

| 1900 ..... | 24,600                                           | 500,000                                                   | 21.30                                                                                                  |
| 1905 ..... | 56,500                                           | 1,265,000                                                 | 56.77                                                                                                  |
| 1910 ..... | 81,899                                           | 2,217,404                                                 | 81.39                                                                                                  |
| 1911 ..... | 87,475                                           | 2,494,773                                                 | 84.69                                                                                                  |
| 1912 ..... | 91,807                                           | 2,588,133                                                 | 85.10                                                                                                  |
| 1913 ..... | 97,023                                           | 2,659,608                                                 | 85.68                                                                                                  |

### THE PRACTICE OF OTHER LANDS.

When we speak of manure out here, we almost invariably understand the term to refer to superphosphate. But, if we look at the practice of other countries, we shall find that the form of manure that is so effective here is not necessarily the one that gives the best results under climatic conditions that are quite different. In countries like England, for instance, the yield of the cereal crops is certainly not in proportion to the amount of super. they use, but practically in proportion to the quantity of nitrogenous manures, such as nitrate of soda, that they apply to the soil.

We owe it to our climate that we do not at present stand in need of these expensive forms of manures. Nitrate of soda, for instance, would cost here something like 14s. per cwt., and in England the standard dressing is frequently 2cwts. per acre, and occasionally more.

On the other hand, we owe it to the general composition of our soils that the use of phosphatic manures is so essential to the raising of profitable crops. In this connection I would like to bring out the

importance of certain questions that deal with the chemical composition of soils. There is no doubt that in the past there has frequently been a tendency to exaggerate the value that attaches to a purely chemical examination of the soil. That this should have been so, however, is easily understood. Farmers were taught that when they applied manures to a soil they brought to the land certain elements of plant food in which the land was lacking, and from this they came to look upon the general question of fertility as being bound up more or less completely in the question of manures, of which the chemical composition of soils was supposed to offer a final explanation. I need not add here that a favorable chemical composition of the soil from this point of view is only one factor in the question of the general fertility of the land, and that however favorable this composition may show in chemical analysis, if other factors are unfavorable, we shall still be faced with more or less unsatisfactory crops. I do not propose, however, dwelling at any length on fertility from its general point of view. What I wish to emphasize here is that the chemical examination of a soil is able to draw attention to any glaring defects in its composition, and as such is useful in determining the type of manure likely to prove successful on any given soil. If there is one substance in which the South Australian soils are deficient it is phosphoric acid, and apart altogether therefore from everyday experience we should be justified in inferring on a mere examination of the general composition of our soils that the use of phosphatic manures would probably be followed by satisfactory results. The figures shown in Table II. will serve to emphasize this position. It should be added that the remarks in this Table, "rich," "poor," &c., do not refer to the general fertility of the soils in question, but to their relative richness in phosphoric acid.

TABLE II.—*Showing Relationship of Phosphoric Acid in Soils to General Fertility.*

Average weight of one acre of soil 1ft. deep = 3,250,000lbs. Percentage of phosphoric acid in soils sufficient to imply normal fertility in the land = 0.1 % = 3,250lbs. per acre, 1ft. deep.

TYPICAL EXAMPLES.

| Origin.                           | Phosphoric Acid. |                        | Remarks.            |
|-----------------------------------|------------------|------------------------|---------------------|
|                                   | Percentage.      | Lbs. per Acre.<br>Lbs. |                     |
| Mount Gambier volcanic soil ..... | 0.179            | 5,817                  | Very rich soil.     |
| Murray swamp land .....           | 0.200            | 6,500                  | "                   |
| Glencoe soil .....                | 0.128            | 4,160                  | Rich soil.          |
| Roseworthy soil .....             | 0.048            | 1,560                  | Moderate fertility. |
| " .....                           | 0.031            | 1,007                  | Rather poor.        |
| Pinnaroo loam .....               | 0.020            | 650                    | Poor soil.          |
| Pinnaroo red sand .....           | 0.015            | 487                    | "                   |

## INFLUENCE OF IMPROVED TILLAGE.

Notwithstanding these facts, however, there has been a tendency in many cases to overstate the value of superphosphate. The reason is that within comparatively recent years the average yields of the State have risen fairly steadily, and since the use of manure has spread during that period, we are often accustomed to attribute these increased yields rather too exclusively to the use of superphosphate. There is no doubt that improved tillage methods have had a great deal to do with the improvement in the yields. I know of one farmer who was a very successful wheatgrower, but who only made a practice of applying phosphates comparatively recently; the secret of his success was good tillage.

The following table enables a comparison to be made between plots dressed with 2cwts. of super., and those which had no manure, at the Roseworthy Agricultural College between 1905 and 1913:—

TABLE III.—*Comparison of Grain Yields of Wheat without Manure and Wheat Dressed with 2cwts. Superphosphate, 1905-1913.*

(Mean results from four pairs of plots. Wheat in all cases preceded by bare fallow.)

| Years.     | 2cwts. Super-phosphate. |      | No Manure. |      | Percentage Increase over No Manure. |        |
|------------|-------------------------|------|------------|------|-------------------------------------|--------|
|            | Bush.                   | lbs. | Bush.      | lbs. | %                                   |        |
| 1905 ..... | 30                      | 11   | 21         | 55   | +                                   | 37.72  |
| 1906 ..... | 20                      | 48   | 17         | 13   | +                                   | 20.81  |
| 1907 ..... | 17                      | 53   | 14         | 36   | +                                   | 22.49  |
| 1908 ..... | 33                      | 53   | 24         | 48   | +                                   | 36.63  |
| 1909 ..... | 29                      | 32   | 24         | 47   | +                                   | 19.17  |
| 1910 ..... | 22                      | 2    | 18         | 18   | +                                   | 20.40  |
| 1911 ..... | 14                      | 38   | 9          | 0    | +                                   | 62.59  |
| 1912 ..... | 19                      | 50   | 10         | 43   | +                                   | 85.07  |
| 1913 ..... | 7                       | 32   | 2          | 39   | +                                   | 184.28 |
| Mean ..... | 21                      | 49   | 16         | 00   | +                                   | 36.35  |

Mean difference per acre—5bush. 49lbs., representing at 3s. 6d. a bushel, 20s. 4d.

It may be said in the first place that results of this kind are of value only when they extend over a sufficiently great number of years. In the present case we are dealing with the results of nine seasons, and in the circumstances the average yields may be looked upon as fairly dependable. We notice that over this period wheat sown continuously without manure since 1905 averaged 16bush. to the acre. This we may take to represent the results of good tillage practices. On the other hand, for the same period of time wheat dressed with 2cwts. of superphosphate to the acre returned a mean yield of 21bush. 49lbs. This represents the results of good tillage, plus manure. We note that the mean influence of 2cwts. of superphosphate is represented by 5bush. 49lbs., or a yield of 36 per cent. better than that of unmanured wheat. At 3s. 6d. a bushel this

represents an advantage in gross return of 20s. 4d., and at 4s. 6d. per cwt. of super. a net profit of 11s. 4d. an acre. A consideration of the last column in the table will show how much greater is the influence of superphosphate in dry unfavorable years like the period between 1911 and 1913 than in more favorable seasons such as 1908 and 1909, and it is perhaps fortunate that the advantages of superphosphate were advocated most strongly in the time of the great drought, when these advantages were far more apparent than they would have been in more favorable seasons. Had it been otherwise, it seems scarcely probable that these manures would have been accepted as readily as they have been. Table IV. shows that the results from the hay crops were very similar in character to those already indicated for grain.

TABLE IV.—*Comparison of Hay Yields of Wheat without Manure and Wheat Dressed with 2cwts. of Superphosphate, 1905-1913.*

(Mean results from four pairs of plots. Wheat in all cases preceded by bare fallow. Hay yields calculated from ripe total produce, allowing for 18 % loss in ripening off.)

| Years.     | 2cwts. Super-phosphate. |       |      | No Manure. |       |      | Percentage Increase over No Manure |

Mean difference per acre—13cwts. 15lbs., representing at 35s. a ton, 22s. 11d.

### FIVE YEARS' PROGRESS.

From Table V. it will be noticed that during the last five years 1909-1913, the average yearly area under wheat, oats, barley, and hay was 2,796,731 acres. The average area of these crops dressed with superphosphate was 2,338,067; the average area of the unmanured crops was 458,664 acres, representing 16.4 per cent. of the total cropped. The average total value of the abovementioned crops was £5,592,866.

The increased yield we noted at Roseworthy from the use of superphosphate is between 36 per cent. and 37 per cent. I have estimated that the increase for the whole State is only 25 per cent., because as a rule smaller dressings are used. Admitting that in the period

under review phosphatic manures have increased the total production of crops to an extent equal to 25 per cent., this increase is equal to the produce from an additional 584,517 unmanured acres. That is to say, that to get the same return, instead of having to crop only 2,796,731 acres, it would have been necessary to crop 3,381,248 acres without manure.

Looking at the question in another way, it will be seen that the average gross return from the above crops has been respectively, from unmanured land £1 13s. 1d., and from manured land £2 1s. 4d., a difference of 8s. 3d. Eighty-three pounds of superphosphate have been used to get this difference; the value of this is 2s. 3d., and it can therefore be said that during the past five years the application of superphosphate has improved the returns from the land on which it has been used to the extent of 5s. per acre over the whole State. Phosphatic manures have raised the gross return from the above crops by £966,840 annually, at an average cost of £347,532, leaving an average yearly profit of £619,308 per cent. Tabulated, the results are as follows:—

TABLE V.—*Showing Value of Phosphatic Manures to the State in the 1909-1913 Period.*

|                                                                             |                         |
|-----------------------------------------------------------------------------|-------------------------|
| Average yearly area under wheat, oats, barley, and hay.....                 | 2,796,731 acres         |
| Average area of above crops dressed with phosphates.....                    | 2,338,067 acres (83·6%) |
| Average area of above crops unmanured.....                                  | 458,664 acres (16·4%)   |
| Average total value of above crops .....                                    | £5,592,866              |
| Increase noted at Roseworthy (1905-13) from use of phosphatic manures ..... | 36% to 37%              |
| Increase from phosphatic manures allowed for the State.....                 | 25 %                    |

*This means—*

1. That in 1905-13 period phosphatic manures have increased total production of above crops to an extent equivalent to an additional 584,517 unmanured acres.
2. That the average gross returns from the above crops have been respectively—

|                           | £ | s. | d. |
|---------------------------|---|----|----|
| From unmanured land ..... | 1 | 13 | 1  |
| From manured land .....   | 2 | 1  | 4  |

3. That phosphatic manures have raised our gross returns from the above crops by £966,840 annually at an average cost of £347,532, leaving an average yearly profit of £619,308.
4. That phosphatic manures have, for the whole State, increased average yields per acre—Wheat, by 2bush. to 2½bush.; Barley, by 3½bush. to 3bush.; Oats, by 2½bush. to 3bush.; Hay, by 5cwts. to 5½cwts.

(To be continued.)

## GRAIN AND FODDER BOARD.

The Grain and Fodder Act was passed by Parliament recently to make extraordinary provision in view of the drought to ensure that there shall be a sufficiency of grain or fodder within the State available for the use of persons requiring supplies. It provided for the appointment of a Board of three, and the Director of Agriculture (Professor Perkins), the Secretary of the Minister of Agriculture (Mr. W. L. Summers), and the Manager of the Government Produce Depot (Mr. G. A. W. Pope) were appointed, with the Secretary of the Advisory Board of Agriculture (Mr. G. G. Nicholls) as Secretary. Under the Act, the Board has power to take possession of any grain or fodder in the State, by serving a notice upon either the owner or person in whose custody it is, notifying its intention to acquire it. Inspectors or other persons authorised by the Board may also take possession on behalf of the Board. Power is given to enter or search any premises or vessels when considered necessary. When the Board makes a seizure it is provided that the price to be paid, if it cannot be mutually agreed upon within 14 days by the parties concerned, shall be determined by the Prices Regulation Commission at the market rates ruling on the day the seizure was made. Power is given to the Governor to make regulations to secure the more effectual carrying out of the Act, and to prescribe a penalty not exceeding £50 for any infringements. The Act provides that when the Board takes possession of any grain or fodder it shall be vested entirely in the Board, and remain its property for the purposes of the Act.

The effect of acquisition by the Board on contracts to deliver is stated:—In case any grain or fodder is, at the time when it is acquired by the Board, in the custody of any person who under any contract is bound to deliver it, or any grain or fodder in lieu thereof, to or in accordance with the order of any other person, the obligation so to deliver shall be discharged upon the taking of such grain or fodder on behalf of the Board, or the delivery thereof to the Board, but without prejudice to any claim which such other person may have to the price or any other sum paid, or to be paid, by the Board for or in respect of such grain or fodder, or to any part of such price or other sum.

Any person resisting, interfering, or obstructing any member of the Board or officers in the exercise of their powers shall be guilty of an offence, and shall be liable to a penalty not exceeding £100, or to be imprisoned for any term not exceeding six months.

The Board is a corporate body, and may sue, and is liable to be sued, in regard to disputes concerning prices, storage, &c.

## DROUGHT RELIEF.

### STATEMENT BY COMMISSIONER OF CROWN LANDS.

The Commissioner of Crown Lands (Sir Richard Butler) has made the following statement with regard to the provisions and administration of the Drought Relief Act passed last session to enable seed wheat and other commodities to be supplied by the Government to settlers affected by the drought now prevailing in the State:—

#### Who May Apply.

Application may be made by any person holding land in a freehold estate under a lease registered in the Lands Titles Office or under any lease or agreement under the Crown Lands Act or any other Act providing for the leasing of land belonging to the Crown, who is as a result of the drought now prevailing in the State, in need of such assistance. Assistance may also be granted to share-farmers, but in such cases the application for relief must be made and the liability for repayment accepted by the landholder, who has entered into the agreement with the sharefarmer. In administering the Act, relief will be given to settlers who are unable to provide or procure money for their requirements.

#### Commodities to be Supplied.

Seed wheat or other cereals, manure, hay, chaff, implements, live-stock, flour, and any other commodities, whether the same kind as any of those before specified or not, which the Minister thinks necessary for the purpose of affording assistance to applicants, will be supplied. Advances to enable applicants to pay for agistment of livestock may also be made.

#### Seed Wheat.

Applicants are required to state on the form the quantity required and the area proposed to be sown, and they are advised that if they can obtain seed wheat true to name in their respective district or elsewhere, they should give particulars in their application, and the purchases will be financed by the department, if approved. If a

man has land in good condition (and applicants when seeking relief are requested to mention fallow and the condition of the land) and his application is otherwise satisfactory, the Government is prepared to provide sufficient seed to sow the full acreage mentioned in the applications. A large number of the farmers are taking advantage of the suggestion that they should purchase seed wheat privately, and it is more satisfactory that it should be so arranged rather than the wheat should be supplied from stocks held by the Government.

#### Provision of Fodder.

Great care has been exercised in dealing with the applications, as it was realised that the supplies of fodder acquired by the Government would have to be conserved as far as possible, as the principal demand for same would be at seeding time. In some cases the applicants have asked for a considerable quantity of fodder, and they have been advised to endeavor to procure the supplies required by purchasing privately either in stook, stack, or chaff, and in such cases the purchases have been financed by the department. The applicants in this way obtain their supplies more cheaply, and it is not necessary to draw upon the department's stock. In many cases, applicants have been asked to procure straw also, and the department has supplied them with molasses to mix with same. A large quantity of hay, chaff, &c., has already been purchased, and steps to obtain further supplies required are being taken.

#### Superphosphate for Farmers.

The Government do not propose to purchase stocks of superphosphates or other manures to be supplied to farmers under the Act, but have arranged for approved applicants to be financed in the purchase of manure required. The applicants are requested to advise the name of the firm with whom they are dealing, and on the application being approved orders to supply, and charge the cost to the department are issued. The distributing firms are asked to obtain an acknowledgment of receipt of the manure on the form prescribed under the Act. It is suggested for the consideration of applicants when choosing the distributing firms, that farmers should support local industry, and thus maintain the livelihood of those employed in the manufacture of manure.

#### Other Relief.

In extremely necessitous cases farmers are being assisted with supplies of flour and other necessities of life, but it is hoped that there will not be many cases to be dealt with under this heading.

Later, it may be necessary to take advantage of the provisions of the Act, and supply implements and livestock to farmers who have not the necessary strength to put in their crops next season, but such assistance will be given only in cases where the officers administering the Act are quite satisfied that the farmers cannot without such aid get in their crops. In administering the Act, the main object in providing relief is to place farmers in a position to crop as much land as possible next season.

#### Advances to Settlers Act.

In the event of a Crown lessee applying for assistance under the Drought Relief Act, and it being found that the land is not encumbered by any mortgage, it is suggested that instead of coming under the Drought Relief Act, he should apply to the Advances to Settlers Board for a loan to place him in funds to reduce any debts he may have, and to secure his requirements in the way of fodder, seed wheat, &c. In such cases he is usually supplied with a limited quantity of fodder to keep his stock going until he obtains a loan, when he is asked to pay the cost of such supplies. In cases where a loan has been recently granted, the applicants are required to purchase the fodder, seed wheat, and manures out of such loan.

#### Repayment of Advances.

The costs of any commodities supplied under the Act are to be fixed by the Minister, and repaid on demand or upon the alienation of the applicant's interest in the lands for which the commodities were supplied. The Act provides that the advances shall be free of interest until the 1st day of February, 1916, but that interest on any advances not repaid before that date shall be charged at the rate of  $4\frac{1}{2}$  per centum per annum, excepting in cases of special hardship, in which circumstances the Minister has power to extend the date from which interest shall be calculated and paid by the applicant.

#### Mortgaged Land.

The fact that land is mortgaged under the Advances to Settlers Act, or otherwise, does not preclude the applicant from obtaining assistance under the Drought Relief Act. Advances under the Act and interest thereon, shall be, and until fully paid, shall remain, a first charge on all lands owned by the applicant at the time when the advance is made.

## CHAFF.

(By F. E. PLACE, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

Chaff, a vet's chaff, light enough to be blown away by the lightest breeze but by an editor's complacency thought to be filling if not feeding, not substance enough in it to raise a horselaugh, but taken as a title because of a question seriously put, "What is the least a horse can live on?" A home-thrust to many a one in seasons like 1914. A cute Yankee is said to have recognised the feeding value of sawdust, and fitted his horses with green spectacles so that they might think it was best alfalfa perhaps, but just as they got used to it they died; and that is what scores of them in South Australia are doing on the irreducible minimum, because what is a living minimum for one is a slow starvation to another, and what will keep a horse at rest will only prolong the agony at work.

Early in the year there appeared in the *Journal of Agriculture* an article (published subsequently as a bulletin, from which the pages are quoted) with a somewhat cumbrous title which we will take the liberty of reducing to "Wheaten hay," which was probably skipped by most readers, and yet each paragraph in it is pregnant with value to the man who has to feed horses, especially when he wants to reach an irreducible minimum.

A good steam engine will return some 15 per cent. of the energy it receives as work; a poor quality horse will return 30 per cent. He is cheaper than a motor by that much, to say nothing of the way he will dig his toes in and haul when the wheels of the engine would skid. He is, however, like the petrol engine, in that to run at all he must have fuel. He is doing work when at rest—his heart is beating, his chest is heaving, his belly from stomach to vent is sifting, sorting, and absorbing; while governing all, his brain and nerves are ever at work. The machine is running silent and true so long as the fuel suits, but switch on the belt, buckle the hames, and your engine is loaded, your horse will want more fuel. That he was using when running light the scientific books call his maintenance diet, and careful experiments have shown that when his working feed keeps him in good condition that five-twelfths of it are used in just keeping the machine running—are required for maintenance only.

Next, the books tell us of energy—a nice Greek form of what we call work—and we learn that all the digestible parts of food help to supply the energy needed. There is a lot of energy stored up on a ton of coal; it may come out as light, and this may provide heat that will make steam that will do work, and if we can get at the amount of heat generated we can soon find out what work can be done. The energy stored up in food has also a definite ratio between the production of heat and work, and tables in "Wheaten hay" show this in a very instructive way.

Now, the work value of 1lb. of digestible starch has been found to be 778 foot tons, and a fair day's work for a 1,000lbs. horse has been found to be 6,500 foot tons, which, divided by 778, gives very nearly 8½lbs. as the amount of digestible starch used up in producing this work, that is in excess of some 6½lbs. required to keep the machine running; but 15lbs. of digestible starch poured down a horse's throat as a daily ration would very soon result in a "stiff un." Other things are needed. Our motor wants different kinds of lubricant for its various parts. So our horse wants things called amides, the things which give the nice flavor and smell referred to in "Wheaten hay." Then that important part of his machinery, his muscles, is always using up proteins—things with nitrogen in them that are found in oats and peas and lucerne and lots of other things, including chaff; and for a horse to get the best results from his food these must be in certain proportions to the starchy and other parts. This proportion is called the nitrogenous ratio, and for a horse at rest should not be less than 1 : 10. Albumenoid ratio is only another name for the same thing, so look at the bottom of pages 21 and 23 of "Wheaten hay" and the chart on page 34. But if the horse is at work we must narrow down this albumenoid or nitrogenous ratio to 1 : 8, or even 1 : 6; that is, we must give corn. A sucking foal, with his rapidly-growing muscles, will be helping himself from his dam's udder to a diet with a narrow albumenoid ratio of 1 : 3. Now, by experiment it has been found that a 1,000lbs. horse requires 0.65lb. protein for maintenance and 0.85lb. for work, totalling 1½lbs. protein for his day's supply at slow steady farm work, perhaps double that if working hard and fast. A 1,500lbs. horse will require a quarter weight more of both sorts, and here again the tables in "Wheaten hay" are worth more than a glance.

Now, the things we have been talking about as starches and proteins existing in the foods cannot be used by the horse in their entirety; it is not a case of straining them out like bluebottles out of a milkjug, only a percentage of them is available; for instance, 10lbs. of good sound oats would only be equivalent to 6lbs. of starch heat units, and 10lbs. of the very best bran would only equal 5lbs., and 10lbs. of wheat straw would give about 1½lbs. Laird and Kyby and Lomond and Katrine tell us this in "Wheaten hay," and we label the news "Mean co-efficients of digestibility."

The 15lbs. starch and 1½lbs. protein required by our 1,000lbs. horse can very well be supplied by one food only. "Wheaten hay" shows us this very plainly, especially in columns 2 and 3 on page 34. We have, however, our pockets to consider as well as the horse's "chubes," as Kipps called them, and it is very rarely economical to feed solely on one food, because the flavor and variety of a mixed diet help to get the greater good out of the smaller quantity. A regular succession of breakfasts of very nutritious cocoa and skilly would willingly be bartered for a cup of tea and a rasher of bacon, infinitely inferior on analysis as work producers; and it is quite possible

that two small sheaves of hay, a two-mile walk for a mouthful of mallee leaves, a blue daisy, and an everlasting or two, to say nothing of the filling sensation produced by half a bucketful of sand may do more toward keeping a horse alive than a weary repetition of a scientifically-balanced ration of chaff without the excitement of foraging round.

But, oh, chaffing vet, you have not given us the irreducible minimum in figures. No: the only answer is that of the Hindu servant cornered for his faults, "Ma'lum nai,"—Don't know. But "Wheaten hay" on page 16 shows that horses doing nothing and eating various kinds of chaff at a rate of about 35lbs. a day, not only kept their condition but gained in weight. Arguing from the experimental figures quoted above the albumenoid ratio was rather too wide, and the quantities of starchy and protein matters less than that demanded sometimes. Still they always got more than the 8lbs. of digestible starch their weight demanded and more than the  $\frac{3}{4}$ lb. of protein, and basing the calculation on hay cut 20 days after full bloom, a fair average sample, 20lbs. of hay and 2lbs. of bran would have kept them going. Less would have kept them alive. The absolute minimum figure lies on the lap of the gods, and lucky the man who discovers it without losing his horses as they get used to it.

## THE WHEAT CROP.

### Official Forecast: Probable Average, 2'19 Bushels.

The official estimate of the wheat and hay harvest was issued by the Government Statist (Mr. L. H. Sholl, C.M.G.) on December 2nd, the Assistant Government Statist (Mr. W. L. Johnston) being responsible for the work of compiling the statistics. Mr. Sholl states that the task of forecasting this season's wheat crop has been the most difficult in his experience. It is fairly certain that between 700,000 and 800,000 acres either failed to germinate or afterwards absolutely perished. The actual figures for the past season and the estimated ones for the present are given in detail in the following pages. In the table below the official totals for the State are shown, together with the estimates of *The Advertiser* and *The Register*.

| 1914-15.                                          | Government Statist,<br>December 1st, 1914. | <i>The Advertiser</i> ,<br>November 12th, 1914. | <i>The Register</i> ,<br>November 10th, 1914. |

|                                                   | Tons.                                      |                                                 | Tons.                                         |
| Aggregate hay yield .....                         | 193,797                                    | —                                               | 250,000                                       |
| Average per acre .....                            | 0'51                                       | —                                               | 10cwt.                                        |

The report shows that the total area under crop is 172,007 acres less than in the preceding season, and the estimated production of grain (4,664,761 bushels) is less by 12,272,227 bushels, and of hay by 225,175 tons. The season has been the driest on record. With the exception of a few isolated stations, all stations show less than half the normal fall. For the wheat-growing period (April to September) many stations registered only from 2in. to 5in. The absence of rain during seeding operations resulted in the seed failing to germinate on large areas, and many thousands of acres of weak growth have been fed off. The average annual rainfall for 52 years for Adelaide is 20·69in., the lowest record being 13·43in. in 1876. A new record is likely to be established for 1914, as the total fall in Adelaide from January to November 30th has only been 10·81in. The total requirements for 1915 are set down at 4,970,000 bushels (2,050,000 for seed and 2,920,000 consumption). The estimated total available, including 1,800,000 bushels (wheat and flour) in stock on November 30th, is 6,464,761 bushels, leaving a balance of 1,494,761 bushels.

The following shows the estimated averages per acre for each division in comparison with the actual for the previous season:—

| Division.                 | Average per Acre.  |               |
|---------------------------|--------------------|---------------|
|                           | Grain.<br>Bushels. | Hay.<br>Tons. |
| i. Central .....          | 3·02 ..            | 0·62          |
| ii. Lower North .....     | (8·02) ..          | (1·12)        |

## REPORT FOR 'NOVEMBER, 1914.

The health of the birds is good. There were in all eight deaths from various causes, viz., two in each section, 1 and 3, and four in section 4. Broodiness is very prevalent this year; in section No. 1 there were 39 cases, and in section No. 3 there were 4; in section No. 4 (general purpose breeds) there were 49; and 35 among the disqualified birds (small-sized eggs). The scores are satisfactory. In the single test a prominent Silver Wyandotte unfortunately died. The weather has been warm, and very hot on many occasions. Rain fell on seven occasions, total 201 points. Green food is abundant.

D. F. LAURIE, Poultry Expert and Lecturer.

## ADVISORY BOARD OF AGRICULTURE.

The Advisory Board paid its annual visit to the Roseworthy Agricultural College on Wednesday, November 11th. The party consisted of Mr. G. R. Laffer, M.P. (Chairman), Messrs. G. Jeffrey, C. J. Tuckwell, A. M. Dawkins, F. Coleman, J. Miller, C. E. Birks, Professor Perkins (Director of Agriculture), Mr. W. J. Spafford (Superintendent of Experimental Work), and the Secretary (Mr. G. G. Nicholls). On arrival at the College they were welcomed by the Principal (Mr. W. J. Colebatch).

Mr. Colebatch explained that the crops were the worst experienced since the introduction of superphosphates, and, accordingly, there was much less to be seen than was usual on the occasion of the Board's visit. A brief tour of the farm was made, however, and the buildings, stock, and equipment were inspected.

### BUSINESS MEETING.

After lunch, the usual meeting of the Board was held and the following matters were dealt with:—

*Fruitpacking Demonstration.*—In response to a request for an expression of opinion regarding the advisableness of the Government being recommended to secure the services of an expert to give fruitpacking demonstrations in different parts of the State, the executive of the South Australian Fruitgrowers' and Market Gardeners' Association intimated that it entirely approved of the idea. Mr. Laffer, on reflection, felt that the time was scarcely opportune to ask the Government to engage the expert, because it was very questionable whether there would be any fruit available for export this season. In nearly all the districts the apples had failed to set, he said, and whether any pears would be gathered would depend upon good rains falling in the near future. After consideration it was agreed, at the instance of Mr. Jeffrey, to hold the matter in abeyance for six months.

*Foxes on Eyre's Peninsula.*—A letter from the Coorabie Branch of the Bureau complained that certain persons had taken steps to send foxes to Port Lincoln, where it was proposed to release them so that they might help to keep down the rabbits, and asked that the Government should be approached on the matter. The Secretary mentioned that in view of the urgency of the question, immediately the communication came to hand it was placed before the Minister of Agriculture, and subsequently, in respect of it, the Surveyor-General had reported that foxes were vermin within the meaning of the Act. The Act provided that—"Any person who lets loose any vermin, or permits any vermin to be set loose in any part of the State, shall, on conviction, be liable to a penalty for each offence not exceeding one hundred pounds, or be imprisoned for a term of not exceeding six months with hard labor." Mr. Jeffrey, in moving that the Government should be recommended to do whatever was necessary to prevent the introduction of the pest to the Peninsula, said although there was not the least doubt that foxes had been useful in some places in destroying rabbits, on the whole the value of their services in that connection had been vastly outweighed by the losses of lambs and poultry due to their depredations. Mr. Dawkins seconded the proposition, which was carried.

## BUREAU BRANCHES.

The Secretary reported generally upon the Bureau Branches on Eyre's Peninsula and upon the visit of the Director of Agriculture and himself to the same. It was decided to formally close the Branches at Lipson and Shannon on account of the absence of evidence of any work being done.

*New Branches.*—Approval was given to the formation of Branches at Waikerie and Woodleigh, with the following gentlemen as members:—  
 Waikerie—E. G. Burrows, T. L. Ninnis, Jas. Murdoch, N. N. Charlton, J. C. Rowe, T. Thompson, Jno. Allen, W. J. Frisby, A. Hall, A. V. Ballantine, J. L. Smith, W. H. Isaacson, F. E. Milner, I. M. McPherson, H. L. McPherson, Frank Dunstone, A. W. Lewis, F. R. S. Goodchild, A. E. Ross, H. F. B. Lehmann, W. G. Ekins, L. B. Pope, J. J. Vasey, A. H. Headland, W. S. Vasey, T. G. Dowling, G. E. Schenke, C. E. Kreusler, E. Miller, J. Miller, F. B. Harden, W. R. Thompson, J. L. Ninnis, Wilson Francis, K. Dunstan, K. A. Norman, S. Pennyfield, E. Jaeschke, L. J. Laycock, R. H. Gill, A. Cabb, A. G. Ifould; Woodleigh—E. T. Smith, F. Day, F. Petch, P. Maloney, G. Good, W. Hammond, L. Good, A. Adams, G. Vogelsang, C. R. Day, N. Day, E. Good, J. Roberts, F. C. Schultz, N. M. Good.

*New Members.*—Yabmana—M. Robertson; Maitland—F. Bowman, C. B. Bowman; Clanfield—F. Hoffmann, W. A. Moar, F. G. Moar, H. R. Hayward, J. Cockshell, A. H. Wilkins; Minlaton—J. Carmichael, C. Newland; Keith—F. Brinkworth; Clarendon—Rev. H. Trewren, S. Tester; Pinnaroo—L. J. P. Roper; McNamara Bore—J. R. Ling; Two Wells—G. M. Cordon; Sandalwood—W. Altman; Naracoorte—C. Malone, J. Clezy, A. O. Forster, F. W. Rochow, W. Busch; Mount Barker—H. Schmidt, H. J. Beasley, W. H. Crozier, M. Matthews; Blackwood—H. H. McKechnie; Claypan Bore—M. Kildea, H. C. Phillis, D. H. Weldon; Clare—L. Jarman; Milang—J. Pearce; Wynarka—I. L. Custance, F. Custance, M. Yates; Coomandook—R. Williams; Lyndoch—H. O. Koch; Carrow—P. Anderson, A. Habibb.

During the afternoon the visitors were the guests of Mr. and Mrs. Colebatch at tea at the Principal's house. When about to depart, Mr. Laffer, in behalf of the Board, heartily thanked Mr. Colebatch for having given the members an opportunity to "look over" the farm, and both himself and his wife for their hospitality.

## EDITORIAL NOTE.

As the position in regard to the shortage of paper, due to the European war, has not been altered, it is still necessary to limit the size of the "Journal." This accounts for the omission of various articles, &c., and a number of reports of meetings of Branches of the Agricultural Bureau.

## THE AGRICULTURAL BUREAU.

### CONFERENCE OF HILLS BRANCHES.

The annual conference of the Hills Branches of the Agricultural Bureau was held at Longwood, on Thursday October 1. The Department of Agriculture was represented by the following:—Hon. T. Pascoe, M.L.C. (Minister of Agriculture), G. Quinn (Horticultural Instructor), Messrs. F. E. Place, B.V.Sc., M.R.C.V.S. (Veterinary Lecturer), D. F. Laurie (Poultry Expert), G. R. Laffer (chairman), C. E. Birks, A. M. Dawkins (members of Advisory Board). A large number of visitors were present, and the undermentioned attended as delegates for the following Branches:—Clarendon—A. W. Biddle, A. M. Taylor, F. B. Brooks, J. Potter; Mount Barker—L. S. Hughes, J. W. Brinkley, E. F. Stevens, H. Smith; Cherry Gardens—H. Lewis, J. Tozer, C. Jacobs, C. Ricks, S. W. Chapman, T. Jacobs, H. Jacobs; Hartley—J. Stanton, J. M. Hudd, W. Bermingham, B. Wundersitz; Blackwood—C. J. Phillips, C. G. Savage, H. E. Sibley; Port Elliot—W. Henderson, H. B. Welch; Forest Range—O. S. Pollard, E. J. Green, H. H. Schulz, J. Vickers, J. Green, R. E. Townsend, F. M. Townsend, F. Green, S. R. McLaren, W. McLaren, Longwood—W. H. Hughes, J. R. Coles, J. Roebuck, J. C. Blackley, J. Brown, H. Winter, E. A. Colley, E. A. Glyde, A. F. Furniss, W. Nicholls, H. Winter, J. H. Brown; Angaston—J. E. Swann; Uraidla and Summertown—F. W. Collins, E. Hart, H. G. Dye, H. F. Johnson, E. Hawke, E. Little, J. M. Bonython, W. Squires; Meadows—G. T. Griggs, W. H. Bertram; Ironbank—J. T. Morgan, W. H. R. Coats.

The chair was occupied by the chairman of the Longwood Branch (Mr. W. H. Hughes), who extended a hearty welcome to the visitors.

### OPENING ADDRESS BY THE MINISTER.

The Minister of Agriculture (Hon. T. Pascoe M.L.C.), in declaring the Conference open, remarked that although at the present time South Australia was suffering many ills, agriculturalists must put on a bold front, and make the best of the circumstances as they found them. It was not desirable to be too pessimistic or too optimistic. The Government and Parliament were not having the best of times at present. When it was considered that already between 5,000 and 6,000 head of stock had been removed from drought-stricken areas to more favorable localities, in order to keep them alive, it would

be recognised that the State was not idle in trying to retain settlers in the outlying districts. Provision had to be made so that if next season turned out well the State would be in a position to reap the full benefits of the good season. Consequently Parliament would be required to consider measures to enable producers, who needed such assistance, to be provided with seed wheat, &c.

He was sure practical men, such as they were, would bring the very best of their intelligence to bear upon the discussions which would take place that day. He noticed that the subject of "Making the Best of Natural Opportunities in the Hills" was to receive attention. This should be productive of interesting and profitable discussion. Another matter of importance—while it did not deal with production, but with making the best out of that which had been produced—was "The Co-operative Grading, Packing, and Marketing of Fruit." Everywhere in the State where fruit was grown extensively; at Renmark, Clare, and various places on the Murray, where it has not been done already, steps were being taken in the direction of co-operative marketing. Uniformity was necessary if they were going to get the best results. This referred also to dairy produce, where uniformity in grading, &c., was indispensable. If the country dairy factories would unite and grade their butter up to a certain standard, and place it on the markets with some distinctive brand, they would be able to demand better prices and compete very successfully with the city factories, with the advantage that, being close to the suppliers, there would not be the likelihood of damage to the cream on account of exposure during long rail journeys. Many acres of these hills, he said, were quite as good for fruitgrowing as those that had already been planted, and he had no doubt that in the future these districts would be producing large quantities of fruit for export purposes.

These conferences had been helpful in the past, and he had no doubt would be helpful in the future.

He expressed pleasure at seeing so many present, and a hope that a profitable day would be spent by all; and declared the Conference open.

### EXPLOSIVES.

The subject of "Use and Abuse of Explosives on the Farm" was dealt with in an address by Mr. J. Potter, of the Clarendon Branch, who, by illustration, showed where charges should be placed in roots, logs, stone, &c., to remove them from the land. He stated that nothing had been found to do post-splitting better than powder. It was a mistake to place a shot in the centre of a log intended to

be split. It should be placed at about 15in. from one end, preferably the smaller. For splitting tough timber he recommended gelignite, and he had never found it necessary to use a saw. The use of this explosive saved time, labor, and money. One man could take out more large stumps with gelignite than could be done by five or six men with a stump-grubber. For the purpose of removing large stumps, a hole should be bored from the centre of the top of the stumps to well down into the roots, and the gelignite placed at the bottom. The quantity of gelignite to use could best be gauged by experience. He advised members to use it sparingly at first, say one and a half plugs, and then increase the quantity if necessary. Better work was often done by one and a half or two plugs than by four. A large stone which had been an obstruction in one of his paddocks for many years was taken out in about 10 minutes by the use of this explosive.

In the discussion which followed Mr. Welch (Port Elliot) said that he had seen gelignite placed under large stumps with good results. Another delegate mentioned that when splitting white gum he had found it better to place the charge in the centre, and not at one end of the log. Messrs. G. T. Griggs (Meadows), and H. R. McLaren (Forest Range), also took part.

#### CO-OPERATIVE DISTRICT FRUIT-PACKING UNIONS.

Mr. F. Green, of Forest Range Branch, read a paper on this subject, as follows:—

We cannot disguise the fact that under existing conditions our export trade is more or less a failure. And when we come to examine the methods that are being employed in shipping fruit to oversea ports, we cease to wonder that our reputation for first class fruit is leaving us. That this state of affairs obtains cannot be gainsaid, and the question we have to consider is how we can regain our lost status. The answer to this question is the establishment of district fruit-packing unions.

Before I proceed in my advocacy of this system it would be well to take a cursory glance at the methods, or, correctly speaking, the jumble of methods, employed in our export trade.

It is well known that no two growers have exactly the same ideas; and when we consider that there are scores of growers shipping fruit, each one of whom has his own peculiar idea of how the business should be done, we come to realise how chaotic the system must be.

To get a thorough conception of this fact, one should spend a season with the fruit inspectors at the Government Produce Depot, Port Adelaide. If the growers could do this I am sure that they would quickly come to the conclusion that some alteration is necessary.

### GRADING DIFFICULTIES.

Let us take a casual glance at the methods employed. First, in regard to grading. Some growers mark their grades by figures, some by A.A., while other employ terms such as choice, prime, or selected. Now, with regard to the first method, viz., marking by figures, this is undoubtedly the best to adopt, but care should be taken to see that a case of apples, say, marked 2½in., contains fruit of that size and no other. In this connection some growers are very careful, grading their fruit to an eighth of an inch, while with others I have seen boxes marked 2½in. fruit marked down to under 2½in. after inspection. So do ideas and methods vary. With respect to marking by A's, I have never seen the slightest approach to uniformity by this method. Growers adopting this method usually class their fruit into three grades, thus, A or AA or AAA, as the case may be; the one A denotes the largest fruit, two AA the next, and so on. Now, where this method fails is in connection with different varieties of apples. For instance, a grower takes a parcel of Jonathans and grades them as I have indicated. He also takes a parcel of Garibaldi and also grades them into three. The Garibaldi being a much larger variety than the Jonathan, the result is that AAA Garibaldi are the same size as AA Jonathan, while AA Garibaldi is equal to A Jonathan, and A Garibaldi is a size to itself. With the method of marking by terms, such as choice, prime, &c., the fault is that such terms express nothing, giving the buyer no indication as to what size apples the case contains, and also the danger of different packers having different ideas as to what is prime, &c.

Under district unions one method could be adopted and all confusion eliminated. Then, in respect to brands, at present there is a confusion of these, every grower having his own private brand. Little lots, from 25 cases upwards, form dozens of parcels, whereas, by the adoption of district unions this could be avoided, as one brand would cover the lot.

Then, take the question of railway freights. For the individual grower to send along 50 cases costs nearly double the amount that would be charged a member of the union, as the latter would send parcels that would load a truck and secure reduced rates.

The same confusion that this complicated method brings about here must surely be considerably increased at the port of destination. Repeated complaints have been made by the salesmen of the trouble these little lots make. It needs no argument from me to show what a great improvement would be brought about by the establishment of some half-dozen district unions.

### BENEFITS OF CO-OPERATION.

Now to the actual benefits to be derived from this system. First, from the standpoint of uniformity. Conferences could be held between the different districts, and an absolute uniform method of grading and marking could be

adopted. If only on this head alone it would be worth while. Second, from the viewpoint of economy. Some people maintain that one of the objections to this method is the increased cost of handling. They say that there are several ways in which individual packing is cheaper. My answer is, there are far more ways in which union packing has the advantage. Opponents to this method say, "Oh, I could do my own packing instead of paying the union rate, and save the cost." Well, even so, it would take time to do it, and time is money; and further, my experience is that at that particular time a grower has plenty to do without packing, and in most cases the grower would find it a relief to have the packing taken off his hands.

Now to the saving to be effected by union packing. The first is in connection with cases. A grower requiring only a few hundred pays full price and gets no discount. A union, buying in large parcels, gets  $2\frac{1}{2}$  per cent. on parcels up to 5,000; 5 per cent. on parcels over 10,000 and up to 20,000; and 10 per cent. over 20,000. Under district unions the cases could be ordered for practically the whole State, and a very large saving could be made. Second, packing material, wrapping paper, woodwool, or corrugated strawboard. In buying in small parcels from the agents, as is the common practice, pretty stiff charges are incurred; but a union could indent this material direct from the manufacturers and thus save 3d. to 6d. per ream on paper and even effect a larger saving on woodwool.

Railway freights I have already mentioned. Thus it will be seen that the saving is considerable, and a far higher state of efficiency is attained.

Thirdly, by the way it would control the export of fruit suitable for the trade. Under existing conditions too much fruit of an inferior quality is shipped, which is having a detrimental effect on the reputation and prices of our fruit. There are growers and buyers who seem to have no idea as to what is suitable for export. Just here I would like to say that the grower who sells his fruit to a speculator stands in his own light. He should keep his business in his own hands. Again, a grower selling outright will often press upon the buyer fruit and varieties that are not fit for export. We should look further ahead and see to it that nothing is sent that will injure our reputation as a fruit-producing country.

#### A WORKING SCHEME.

I should now like to say something on the method to be adopted in successfully carrying out the idea. Every community of orchardists should unite and establish a packing shed in a position that will be the most advantageous; one shed for each district if possible. A secretary should be appointed to work in conjunction with a committee of, say, four of the most reliable growers. Rules should be adopted that will give this committee power to see that the standard of excellence I have advocated is maintained, and that all fruit failing to reach this standard be rejected. This committee should

also be empowered, in conjunction with the secretary, to make all arrangements for the supply of requisite material. A stock book should be kept at the shed for booking deliveries of fruit, thus, grower's name, quantity delivered, variety, how many packed, and how many of each grade. If this is kept up to date little trouble will be found in tracing out individual growers' lots from the account sales. I do not believe in pooling proceeds. Under the system I have briefly outlined each grower gets the return according to the quality of the fruit shipped. For instance, one grower may go to considerable trouble and produce most of his fruit first and second grades, while another, not so careful, will have most second and third grades. I believe that the man who produces the best fruit at, perhaps, considerable trouble, should have full value for the superior fruit produced. Unless he did so there would be no encouragement to produce the best, a thing most essential to success.

No highly-paid or "white collar" official should find a place in the union.

The secretary, on whom most of the work falls, is the only one who should receive any payment, and he should be paid at so much per case, that is, a levy should be struck on every grower, for argument's sake, say, 1d. per case. Thus, if one man sent 500 cases he would pay 500 pence; another sending only 50 cases would pay 50 pence, and so on *pro rata*.

Before concluding I would like to deal briefly with another aspect of this question, and that is in connection with local cool storage. The present method is for the grower to sell his fruit to the merchant, who stores it, and then brings it on to the market in competition with our home-stored fruit. Under the system of district unions we could do our own cool storing and keep control of the markets to our own advantage. However, this is a subject which needs a paper to itself and it is an aspect of the question I have merely mentioned in passing.

Mr. J. E. Swann (Angaston), addressed the gathering on the same subject. To make the fruit industry a success, he said, it would be necessary to establish unions in every fruitgrowing centre. For instance, for a number of years apple growers secured 3s. 6d. to 4s. per case for Cleopatra's. The price then dropped to 3s., and then to 2s. 6d., although a case of these apples could not be grown for less than 3s. or 3s. 3d. There was a lack of uniformity on account of the different ideas of packing and grading held by different men. Further, the individual shipper had a certain space allotted him in the ship. If at the time of shipping he had insufficient cases of a good class of apple, he would fill up with a few cases of inferior fruit. Thus the reputation of South Australian fruit suffered. Since the formation of a co-operative union in his district the price had not dropped below 3s. 3d. per case. By co-operating it was possible for growers to obtain requirements such as paper, wood wool, cases,

&c., more cheaply. In his district all the apples dealt with by the union were graded and packed by hand. This method was rather slow, but very efficient.

Mr. Swann then detailed the principles by which the Barossa Fruit Growers' Union was governed, and mentioned that as a result of last year's work, the net return to orchardists worked out at 4s. 6½d. per case for apples.

Mr. G. R. Laffer, M.P., said that if the fruitgrowers in each centre co-operated, and graded and marketed their fruit, it would bring better prices. With regard to mechanical graders, he had seen some machines which would put through 400bush. per hour, and some would grade as many as eight distinct sizes. This system of grading enabled the cases to be correctly marked on the outside, with the number of fruit each contained. Packing could be done much better and more cheaply in a union packing shed. He was a strong supporter of co-operation among fruitgrowers.

Mr. McLaren (Forest Range) considered that in the districts where many varieties were grown, a difficulty would arise in pooling the apples, but Mr. Swann said that he had found pooling desirable.

The Horticultural Instructor (Mr. Geo. Quinn) favored district packing sheds which could be secured by growers co-operating. He had, whilst in Tasmania, seen a machine which graded very exactly without bruising the fruit. If the fruit were packed by machinery, the cases could then be branded as containing a certain number of apples. Branding on each end of the case was a splendid idea.

Mr. C. Ricks, of Cherry Gardens, moved—"That this Conference endorses the value of co-operative packing sheds in the fruit-growing districts, and that the various Branches interested be asked to consider the question with a view to taking steps to bring about the establishment of co-operative unions." Mr. T. Grigg, of Meadows Agricultural Bureau, seconded the proposition, which was duly carried.

### NEXT HILLS CONFERENCE.

It was decided to hold the Conference at Clarendon next year. A vote of thanks moved by Mr. Nicolle (Meadows), and seconded by Mr. Blackley (Longwood), was accorded the Hon. the Minister of Agriculture (Hon. T. Pascoe, M.L.C.).

### THE HORSE'S FOOT.

The Veterinary Lecturer (Mr. F. E. Place) gave an interesting address on this subject. He explained very fully the construction of

the foot, and also the work performed by each separate part. Mr. Place then answered a few questions put to him with reference to different ailments of the foot, and gave some hints on shoeing.

### DAIRY FARMING.

In the absence of Mr. J. Chibnall, Mr. H. B. Welch, of Port Elliot, read his paper on this subject, as follows:—

Two essentials to dairying are suitable locality and a natural love of animals by those employed. There is not a more intelligent animal on the farm, or one that will respond to kindness more, than the cow. Of the different milking strains of cattle I prefer the Milking Shorthorn. If she is rightly bred she will fill the bill as a dual purpose cow. I prefer a cow of medium size, as two of these will live on ordinary pasture where a large cow will starve. The principal points are that she should be broad across the loins, thin shouldered, and broad chested. She should have a well-shaped udder with brown teats. As to her capabilities as a milker one cannot have a better guide than the milk escutcheon. The color of the skin seems to indicate the color of the butterfat in the milk, and it seems to me that a dark-orange butterfat will make a better quality butter than a very light-yellow butterfat which appears to me to contain more stearine, consequently the butter made from the latter is harder. On natural pastures for cows the feed should be succulent. The ordinary native root grass is no good whatever for producing milk. At night the cows should be placed in a different paddock from that in which they have been feeding during the day. It does not matter so much if there should be no water unless the feed is dry. But in the paddock on which they graze during the day they must have continuous access to water. Green feed should be grown to help them through the winter. I have found that Chevalier barley makes the best green feed and is not so coarse as Cape barley. If one can grow lucerne this is all the better for summer feeding. This feed should be allowed to wilt before being given to cows. If one can sell the milk at 1s. per gallon it will pay to go in extensively for growing feed; but if only selling butter which, taking the year round, gives a return of about 4½d. per gallon owing to price of labor, there is not much in it. However, a good deal can be done by giving the cows the first choice of the hay and stubble paddocks. There is also a return from the skim milk, which is worth about ½d. per gallon for feeding pigs and calves. Unless one can make 2s. per week from the pigs for every week one has them there will not be much profit. If one is feeding calves for market or to keep, I recommend the patent rubber teat. The metal tube obtained with it soon gets out of order. If the young calf is allowed to drink more than it can properly digest, impaired digestion, and, later on, dry bible will result. As Adelaide extends most of the milk will have to come from the country districts, and there will be depots at various railway stations where the milk will be treated and sent or delivered to customers in sealed bottles.

Mr. J. Potter (Clarendon) said that the native root grass was a very good milk producer, but Mr. J. Stanton, of Hartley, agreed with the writer of the paper that root grass was not a good milk producer, but he had found that butter made from milk of cows fed on this grass was of good quality. Mr. Hudd (Hartley) favored the Jersey, as the milk from this cow was richer in butter-fat than that of the Shorthorn. A good cow, he said, should milk for eight years. Mr. C. Ricks (Cherry Gardens) recommended resting and manuring portion of the grazing paddock each year, otherwise the grass became very poor in quality. He preferred the Ayrshire-Jersey cross, which he considered stood climatic conditions better than the Jersey. Mr. A. M. Dawkins (Advisory Board) considered that the Jersey gave the largest milk return for the quantity of food consumed. A good cow should average 9lbs. or 10lbs. of butter per week. He considered the dairy cow should have the very best of treatment and fodder.

### FRUITGROWING.

This subject was dealt with in a paper by Mr. E. Hawke, of the Uraidla and Summertown Branch, as follows:—

To a casual observer the truth must come home that we are as yet in our infancy as far as fruit-growing is concerned. The bulk of the land through the Hills and to the south is eminently suitable for fruit-growing, and the greater part of this is still in its natural state. Although during the past 20 years thousands of acres have been planted with fruits, there is as good, if not a better, market for fruit now than there was at that time. For instance, this season all jam fruits and every other class of good fruit sold extremely well, and I think we can look forward with every confidence in our fruit-growing industry. To be successful we must only plant the very best of each kind of fruit. Another very important point is that we must only plant varieties that are suitable to our own particular class of soil. The Jonathan is without doubt one of our best apples, but it will not do well everywhere. It will thrive in good chocolate land or in sandy loam with a clay subsoil. In either of these soils it will come into bearing quicker than most varieties of apples. In our district the Rome Beauty does well in any soil if worked properly. When planting I recommend the Glengyle Red or Red Rome, as it has a much better color, and any fruit with a good appearance is sure to command a ready sale and good price. The Cleopatra is a splendid apple, but I am doubtful whether it is profitable to grow in our moist Hills districts. To make sure of getting a crop one needs to be continuously spraying. I prefer The London or Five Crown Pippin. The quality is almost as good, and it is a splendid cropper and very easy to keep clean.

In the case of a person taking on an old orchard, I advise him not to be too drastic in cutting the trees back, but to work them down gradually. If they are cut too hard, in time a good many dead branches will result. The best way is to thin out the tree so that it will bear marketable fruit. Second-class fruit is better than none. Keep on planting young trees, and as they come into bearing work out the old ones. If they are not worked on blight-proof stocks do not graft new varieties on them, but take them right out and plant new trees. It will pay better in the long run.

In preparing new land for an orchard much depends on the nature of the soil. If the land is of a loose nature it does not matter so much about breaking the soil to any great depth, but if it has a hard subsoil it is necessary to break it deeply. I believe it would pay to use gelnite to break up some of the stiff land. Some vinegrowers have used it successfully. After planting, work the land well around the trees for the first few months, to keep it as moist as possible. I am not in favor of growing market peas between young trees, as they make the land too dry. The most critical time in the life of a tree is the commencement of summer, and the peas by that time, unless a very wet spring has been experienced, have drawn heavily on the moisture supply of the land. I would prefer working the land during the spring, and then with the first rain after the new year sowing a crop of swedes, which, I think, will pay better than peas, as there is always a good sale for them. They are a splendid pig food, and the trees will have the advantage of the land being manured for the swedes.

We can plant gooseberry bushes or strawberry plants the first year without any harm if we keep the land well worked.

The varieties of apples I favor are—Early, Williams' Favorite; early and late, Astrachan, Worcester, American Mother, Emperor Alexander, Maiden Blush, Jonathan, London Pippin, Glengyle Red, or Rome Beauty. Cherries—Purple Guigne, Knight's Black, Tartarian, Biggareau Napoleon, St. Margarets, and Up-to-Date. If we could be sure that the Japanese plums would not suffer from disease I would advise planting Burbanks, but it would pay to grow Reine Victoria, Coe's Golden Drop, and Monarch. During the past few years gooseberries, strawberries, and raspberries have brought paying prices.

To produce good fruit the land requires to be supplied with nitrogen, phosphoric acid, and potash. There are complete manures on the market, but I advocate manuring one year with bonedust and potash, the next year with sulphate of ammonia and bone super. Some gardeners recommend blood manure, others sulphate of iron. During last season one of our gardeners had a record crop of fruit all round. He attributed it to sulphate of iron, which he used as a spray and manure as well. Without spraying much of our work would be wasted. In the spring we must spray to combat fusieladium. I know of nothing better than Bordeaux mixture, although

some claim that the lime-sulphur mixture is as good if not better than this. I do not think there are many who doubt the efficiency of arsenate of lead for destroying codlin moth.

In conclusion I might add when buying young trees, purchase them from a reliable nurseryman. The trees should have plenty of fibrous roots. I advise planting fairly early, to ensure the roots getting a good hold before the dry weather comes on. We cannot lay down any hard and fast rule in pruning. Different varieties require different methods; we have to study the habits of the trees and use our intelligence.

In opening the discussion on this subject, the Horticultural Instructor (Mr. G. Quinn) told members that the system of manuring recommended in the paper should prove beneficial. He considered that the ranges south of Adelaide would eventually become the main fruitgrowing areas. Each locality should confine itself to a few good varieties. He did not agree with planting vegetables in between the rows of trees. Early planting was best; the ground was then warm, and not too wet.

Mr. W. Nicholls (Longwood) said that Jonathon, Rome Beauty, and London Pippin were the most profitable in his district. He was inclined to think that the extra cultivation given to the crops between the trees more than compensated for the amount of moisture taken from the ground by vegetables grown between the rows. He would not apply nitrogenous manures.

Mr. A. M. Dawkins agreed with the writer of the paper, especially in regard to not growing vegetables between the trees. He had taken out unsuitable trees, cleaned out the hole, filled it with a suitable manure, and placed a young tree in the hole straight away with good results.

### BITTER PIT AND FUSICLADIUM.

Mr. C. G. Savage, of the Blackwood Branch, read a paper outlining some of the conclusions published by Mr. D. McAlpine, who has been investigating this defect on behalf of the Federal and State Governments for several years past. He also detailed some of the results recorded thus far relative to this disease in the experiment plots at the Government Orchard at Blackwood.

Briefly summarised, Mr. McAlpine's contentions claim that bitter pit is due to the vascular network, which ramifies the pulpy tissues of the fruit, being broken, or failing to form or extend in keeping with the demands of the softer pulpy tissues—of which it is the irrigating system—for liquid nourishment. This vascular system enters the stalk of the fruit, and passes around the central carpellary cavity in the pulp, usually as 10 fibrous bundles, which in

turn subdivide and ramify throughout the whole of the pulp cells, reaching to within a fraction of an inch below the skin, where the much-divided capillary-like meshes envelope groups of cellular tissue. It is thus that every part of the growing fruit is kept supplied with mineral salts, drawn from the soil in solution by the roots, as well as the more fully elaborated sap prepared by the functional processes of the tree as a whole.

The bitter pits or brown patches of tissue arise, in Mr. McAlpine's opinion, when, through fluctuating conditions of moisture and humidity, the transpiration through the skin of the fruit is materially interfered with, either by reduction below the minimum which is safe, or forced to excess by an over-abundance of sap. In plain terms, the lack of an even and sufficient supply of sap at all times makes for bitter pit. Passing to the question of how this regular supply can be maintained, the fruitgrower is met with difficulties, owing to the many diverse factors which, under Australian climatic conditions, operate to prevent this undisturbed course persisting throughout the period when the apples are upon the trees.

The prevention, as far as practicable, of a loss of soil moisture through surface evaporation by means of good tillage, the restriction of pruning to such operations as will not unduly disturb the balance of the sap's course, fertilising the soil with manures of a well-balanced composition, and moderate irrigation where deficiency is feared in moisture from natural sources, are put forward as a combination likely to most nearly approach the needs of the tree in bringing to maturity a non-defective crop.

After the fruit is gathered the bitter pit often develops in the store if the temperature and humidity fluctuates in that structure, consequently the maintenance of a very low, even temperature is desired.

The experiments in the Government Orchard at Blackwood deal with the influence of various stocks, as well as different forms of pruning, thinning of fruit, tillage, and kinds of manures. Those relating to stocks and fertilisers have been in operation longest, and the trees are now beginning to bear fruits in varying quantities. In four out of five instances the trees worked upon Dunn's Seedling stems, grown on Northern Spy roots, showed less bitter pit than those on Spy only, or Spy with Rokewood intermediate stem.

The fruit from the manured plots gives most contradictory results so far, as instanced in three rows of unmanured check trees, of which the fruit from one occupies second position in its freedom from the defect; two other check rows are placed in 11th and 13th

positions. One thing appearing to be pretty well consistent is the greater the crop on a tree the less the bitter pit affects the fruit. In the pruning and tillage tests the trees are not sufficiently advanced in fruitfulness to offer any information worthy of note.

It may be pointed out that last season the proportion of pitted apples on the horizontal limbs exceeded that of the upright ones—a result not usually accepted.

### BLACK SPOT OR FUSICLADIUM.

Mr. Savage gave an outline of trials carried out by Mr. McAlpine in Victoria during some 10 years with fungicides, principally Bordeaux mixture and Burgundy mixture, for the suppression of this fungus. In those conducted at Pakenham in 1901-2 the Bordeaux mixture, with 1lb. common salt added to each 50 gallons, gave a higher percentage of absolutely clean fruit, viz., 67 as against 57 and 48 by the ordinary 6,4,50 Bordeaux or 6,6,50 Burgundy respectively. Other tests, however, revealed very little advantage—certainly not more than that attributable to experimental error—arising from the addition of salt, &c., to the ordinary Bordeaux. Of the formulas tried for Burgundy mixture the 6,7,50 gave the best results to Mr. McAlpine.

The time selected for giving the first spraying is just as the leaf stalks begin to show, and if a second application is necessary, just as the apples are forming distinctly. In other tests a pink tinge in the unopened flower buds was accepted as the most suitable time to apply these protective fungicides, both of which appeared capable of doing really good work.

In discussing Mr. Savage's paper, a delegate said he had noticed that bitter pit did not affect fruit grown in sand, while trees grown in clay in an adjoining paddock had suffered; but Mr. Nicolle (Meadows) had found Cleopatras grown in sand as badly affected as those grown in clay. A delegate instanced a case where he had sent 100 cases of Cleopatras into the cold storage; subsequently one case was found to be badly affected with bitter pit, while all the others were quite sound. These apples had all been picked at the same time from the same trees.

### CLEAN SEED WHEAT.

Mr. J. M. Hudd, of Hartley, moved, and Mr. C. Ricks, of Cherry Gardens, seconded, that "This Conference suggests to the Advisory Board of Agriculture that it bring before all Branches of the Bureau in the wheatgrowing areas, the matter of keeping the

different varieties of grain separate, and distinctly branding the bags, so that wheat distributed amongst farmers in the drought-stricken districts will be of sample true to name."

### MAKING THE BEST OF NATURAL OPPORTUNITIES IN THE HILLS.

This subject was dealt with in the following paper by Mr. C. Ricks, of Cherry Gardens:—There is an idea current amongst a number of people that a very large portion of these stringy-bark ranges is useless country. Admittedly there is a portion of little value for grazing purposes, but for fruitgrowing and dairying there is a great future before these hills. Even with many of our roughest hills the time is not far distant when it will pay to clear this land and grow timber. Pines will grow in the most exposed spots. The kinds to grow could be ascertained by experiments in different places. I question if there is a country in the world with a climate as suitable for so many different varieties of fruits as the district between Belair and the Meadows. Some of the best fruits produced in South Australia, if not in the Commonwealth, are grown here. At Upper Sturt and Ironbank I believe the best strawberries in the State are produced on what is termed poor stringy-bark land. Apples, pears, plums, cherries, oranges, lemons, peaches, and apricots—in fact, nearly all fruits that grow in Europe—have been grown largely, and during the last few years Japanese plums have been introduced with equal success. The same might be said of vegetables. As to whether we are making the best of our natural opportunities, my belief is that in many cases we are not. The question may be asked, "What are our natural opportunities?" First, a splendid climate; second, a fair amount of good land; third, a good supply of fresh water, in many cases on the surface, and at other places at a reasonable depth. It will be in the use of the water that the greatest benefits will be gained in the near future. It is well known that five acres of land irrigated for at least six months of each year will produce more fodder for stock than a hundred acres without the water. The land in the hills will produce 100 per cent. more feed in the summer months, when water is applied, when the soil is warm, than it will in the winter, when the soil is cold. In the very near future these hills will supply Adelaide with fresh milk for at least six months each year, and the Lower North the other six months. In addition to that, I consider that if the best use were made of our water supply we should be able to supply our own people with butter. It is not to our credit that we have had to go to the other States for our butter.

In time it will pay to erect weirs in many places along the Onkapinga River. There are many places where large volumes of water could be impounded in this way at a reasonable cost. We, as a people, have not fully realised the value of water as a factor in the production of wealth—only in a small way, such as in market gardening and in some few cases the growing of fodder for stock is this recognised. Take a season like the last. What would it have meant to stockowners if each had a few acres of irrigated land? December, January, February, and March, in ordinary seasons, would be the only months in which—in the hills—we would require to irrigate for fodders. There is not the same amount of water required in the hills to produce a crop of fodder that is necessary on the plains. Evaporation is not so great, as we have cooler nights. We should also note the advantage of using sprinklers, over the old system of running the water on the land. I consider that 100galls. of water applied by means of sprinklers is as efficient as 300 under the old method of flooding. The water is more evenly distributed. It was always a difficult matter to control water running on the hillsides. With the sprinklers, a little attention occasionally is sufficient to regulate the water, so that very little will go to waste. Personally, our property consists of 97 acres—some of it very rough and stony—poor land for cultivating purposes. We cultivate about 15 acres, in four different parts of the section. Three acres of it is not of a convenient shape and situation for working with horses. We have four acres of fruit trees, consisting of apples, pears, plums, cherries, oranges, and lemons. The balance is used for potatoes, other vegetables, and fodder for stock. For the last 10 years we have averaged 30lbs. of butter per week for sale, not counting the butter or milk for the family. This we should never have been able to do had we not made use of water. In the early part of June we had barley 2ft. high. This season that meant a lot to us, as everything has been at a high price; and with the aid of other foods the cows did not lose condition. Now that the feed is growing they will pay for the extra attention through the critical period. We should hear little of dry bible if more attention were devoted to getting the stock a little green feed through the dry part of the season. The water we use is secured from a well 50ft. deep. It yields a fair supply. An oil engine is used for pumping, and pipes are laid over the land, with hose and sprinklers attached. In another place, where there is a surface spring, we sank a large hole, and connected it with pipes and hose and sprinklers. That is a cheap method where one has the necessary

height to run the water by gravitation. In order to get over the difficulty of the cost of labor, I would suggest that those persons who have more land than their families can work, should either sell or let on such terms that many of our young men and maidens could make a home for themselves. By that means the labor problem and also the population question would be solved, and the Commonwealth would be the richer for it.

### **EVENING SESSION.**

#### **POULTRY FOR EGG PRODUCTION.**

Mr. E. W. Beythien (Longwood) read a paper, in which he said:— It seems to me that not more than one man in 20 can be brought to look seriously upon egg-farming as a business, and there is abundant evidence that the majority of those who undertake poultry farming in any of its branches do so because the idea is prevalent that it is an easy way for a tired man to make a living. Never has a greater mistake been made. In no other industry is the dividing line between success and failure so narrow or so easily overstepped, and unless the man who thinks of striking out in this direction is willing at all times and in all weathers to be at his post, and give his birds every care and attention, he would be well advised to try something else for a living. However, if a man is convinced of his ability to perform his duties thoroughly, the first and most important thing in making a start is to select a suitable locality—for fowls will not do well in any place, as some people imagine. What is required is a well-drained, well-sheltered, sunny slope, facing about north-east, or as near that as possible. It has been proved conclusively that birds lay best in semi-confinement. Houses and yards should be erected on this slope in a systematic and orderly manner, in order to make feeding, watering, and cleaning generally as easy as possible, for labor saved is money gained. In the Hills it will be found that houses on the scratching-shed principle easily rank first, and as for design and general details of these, one cannot do better than follow the advice of the Poultry Expert (Mr. D. F. Laurie). The scratch shed advocated by him seems to me just the thing to fill the bill in these parts. Houses for breeders, to contain 10 hens and a rooster, and for the laying pullets and hens (each capable of stocking 100 birds) should be in-

**stalled.** As far as I am concerned, the bottom has been knocked out of the argument that birds do better in hatches of 10 than in flocks of a 100—it all depends on the attention they get. Of this I am convinced—if large flocks get the same care and attention in proportion as small ones, they do equally as well. For egg production at present only one breed of fowl should be kept, i.e. the White Leghorn. All the world over this breed has easily outclassed all others. Although one often is told that other breeds can be built up and made just as profitable, the man in the business will find he has neither the time nor the money to waste in such experimenting. What he wants is the breed that has already proved itself, and it can safely be left to the backyarder or the man who keeps fowls for a hobby to work up and prove another and a better breed, if possible. However, all White Leghorns are not heavy layers, so one should be sure to get a good laying strain to start with. On reading the "Summary of Results" from the various egg-laying competitions, one will notice that so many pullets laid so many eggs in 12 months, and returned a profit of so much over cost of feed. Read superficially, this sounds very nice; but of all those who read, to how many does it occur that every one of those pullets was bred to commence laying on or about April 1st. Think that well over, and one has the secret of successful egg-farming in a nutshell. Pullets bred earlier invariably go into moult or partial moult when eggs are at a high price, and those bred later, instead of laying at from five months to six months, take from seven months to eight months, or even nine months, to mature, and so start laying when the high prices are over, and the cream of the market is lost. From a strictly business point of view, neither is profitable, so it simply amounts to this: To be successful at egg-farming a man must have sufficient incubator and brooder capacity to hatch out during six weeks or so of each year, and afterwards rear at least one-half of the laying birds he intends to work as his standard. This, of course, is on the principle of keeping his birds only two years, which is their limit as far as profit is concerned; pullets for layers and first-year hens for breeders. In mating select only those hens which have deep, broad breasts and deep, long underbodies, for the former denotes a strong constitution and the latter conforms with the general type of egg-producers. The bird must have stamina, and also size. As regards the cockerel, the utmost care should be taken in selection. The bird should be of an approved laying strain, and hatched from an egg that scaled over 2oz.

Fowls with strong constitutions are the most profitable for egg-production, and it will be noticed those that are robust and vigorous will pass through the moulting period quickly, and hardly stop laying, whilst those of a weak constitution usually go in the legs and stop laying for a month or even two months or three months at this time, and are afterwards of no use as breeders—their progeny being weak and sickly. Then comes the usual lament on chicken mortality. It is advisable to mark all the vigorous, early-laying or quick-maturing pullets with a colored leg band; then these can be watched through the year, the leg band to be taken off if anything unsatisfactory happens to any one of them, or if they do not come up to expectations in other respects. This means close observation of the birds, but it is worth it, for the stamina of the future stock depend upon it. In regard to feeding, good sound commonsense, and also good sound foodstuffs, are needed. Feed a variety, so that the fowl can balance its rations. Feed just in sufficient quantity and no more, and, above all, feed regularly and systematically every day in the year. The food ration should contain all the elements needed to keep the birds in good condition and also furnish what is needed to make eggs. Never, under any circumstances, force a bird with irritants. Although the general method is to feed mash in the morning, and cram the bird with grain at night, I reverse the order of things, and give a light feed of grain in litter in the early morning (thrown in overnight), abundance of green feed at midday, and as much mash as the birds will eat readily in the evening, and my reasons are these: If the morning mash is fed carelessly, or without judgment, the birds fill themselves, and so become fat and lazy. It is often said that mash should be fed in the morning, because it is more readily assimilated; but because it is more readily assimilated is really the reason why it should be fed at night. To my mind, mash fed in the morning, combined with a heavy, solid grain feed at night, only means more or less poor restless birds at night, and tired, dull, lazy-looking birds by day. If the appetite fails the birds should be tempted with titbits or a change of diet, sometimes, perhaps, a tonic is advisable, for one thing is certain—if they cannot be made to eat they will not lay. Chickens should be allowed free range from the time they are strong enough to leave the brooders. Divide the sexes as soon as possible, and always place the pullets in the quarters destined for them as soon as they show signs of properly combing up, and so enable them to become accustomed to the different conditions before starting to lay.

There is a comfortable living in egg-farming, if it be carried out in a strictly business-like manner—not otherwise. Thoroughness is the one word that sums up the whole thing. Use method, and always be on time, for only by being regular yourself in all things can you induce your fowls to lay regularly. Keep records of everything, and always be on the watch for leakages. Cull out at intervals, and doctor a sick fowl with an axe only. Give the fowls first place, no matter what else has to slide, and remember this—that if a person goes in for egg-farming, he must go in for egg-farming and nothing else. For if a man desires to make a success of it he must apply all his energies in this particular direction, and he will then find that egg-farming is by far the most profitable of all the different branches of poultry-farming.

The Poultry Expert (Mr. D. F. Laurie) then delivered an address.

Near Bridgewater.

## THE WHEAT MARKET.

| Date.  | LONDON (Previous Day).                                          | ADELAIDE.<br>Per Bushel.            |

| 4      | Firm, with fair inquiry .. .. .                                 | 5/4½ to 5/7½                        |

In New South Wales the price of wheat as officially fixed was 4s. 6d. ; on November 19th the Government introduced a Bill giving them power to buy all wheat at 5s. At the date of writing this measure was still being discussed. In Melbourne the official rate to November 17th was 4s. 9d. ; it was then raised to 5s. 6d. On December 3rd the further announcement was made that the official rates were abrogated, and trading on ordinary lines was resumed at a considerable advance.

## DAIRY AND FARM PRODUCE MARKETS.

A. W. Sandford & Co., Limited, report on December 1st—

**BUTTER.**—The sultry weather experienced in the early part of the month was responsible for the poor condition of many usually very good lines of butter. For anything approaching condition and quality the demand has been very active, but weather-affected lots have met a dragging sale, so that the range in prices has been wide. "Alfa" sold at 1s. 2½d. per lb.; "Primus," 1s. 1½d.; third grade creamery, 10d. to 10½d.; choice separators, 11d. to 1s.; well-conditioned store and collectors', 9½d. to 10d.; heated lots, 8d. to 8½d. per lb.

**EGGS.**—Throughout the Commonwealth very low rates have been ruling, and with Western Australia self-supplying, the market here has been a depressed one. Guaranteed hen sold at 7d. per dozen; duck, 8d.

**CHEESE.**—Values are easier owing to importations from the neighboring States being placed on this market. Present quotations, 6d. to 6½d. per lb. for large to loaf.

**BACON.**—The turnover has been extensive, without any quotable alteration in price. Hams are finding a seasonable inquiry, buyers purchasing for Christmas. Best factory-cured sides, 8½d. to 9½d. per lb.; cooked hams, 1s. 1d.; uncooked, 11d. to 1s.; lard in skins, 8½d.; bulk, 7½d. per lb.

**HONEY.**—Large parcels of new season's take are now arriving, but the active demand readily clears all lots. Prime clear extracted, 3d. to 3½d. per lb.; beeswax, 1s. 2½d. per lb.

**ALMONDS.**—Only odd consignments offering, and purchasers are now asking for quotations for the new crop. Brandis, 7½d.; mixed softshells, 7d.; hardshells, 4d.; kernels, 1s. 7d. per lb.

**LIVE POULTRY.**—The pennings throughout November have been very extensive, and where quality was right very nice prices were secured. Unfortunately a heavy proportion consisted of birds that were in poor condition, and as demand for these was slow, low prices ruled. Geese met a very brisk sale, buyers purchasing in anticipation of Christmas trade. Good table roosters are worth 3s. to 3s. 6d.; nice conditioned cockerels, 2s. to 2s. 6d.; plump hens, 1s. 6d. to 1s. 10d.; light hens and poor-conditioned cockerels, 1s. to 1s. 3d.; ducks, 1s. 10d. to 2s. 6d.; geese, 4s. to 4s. 6d.; pigeons, 4d.; turkeys, 7d. to 9½d. per lb. live weight for fair to good table birds.

**POTATOES AND ONIONS.**—A few old season's potatoes are still arriving from Victoria, but the attention of buyers is now chiefly centred upon new ones. Locally, these are a partial failure, and additional supplies are being obtained from the other States. Onions.—Local deliveries are on the short side, and imports from Victoria are being utilised to make up the shortage. Present quotations—Potatoes, old, £7 per ton; and new, £14 per ton of 2,240lbs. on trucks, Mile End. Onions, £13 per ton of 2,240lbs. on trucks, Mile End.

## RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of November, 1914, also the average precipitation to the end of November, and the average annual rainfall.

| Station.                   | For Nov., 1914. | To end Nov., 1914. | Av'ge. to end Nov. | Av'ge. Annual Rainfall | Station.               | For Nov., 1914. | To end Nov., 1914. | Av'ge. to end Nov. | Av'ge. Annual Rainfall |

\* No report received during the month of November.

† Formal report only received.

‡ Held over until next month.

## ADVISORY BOARD OF AGRICULTURE.

## Dates of Meetings—

January 13th, 1915, and February 10th, 1915.

## THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

### REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

#### UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

**MORCHARD** (Average annual rainfall, 11in. to 12in.).

October 3rd.—Present: 13 members.

**POULTRY ON THE FARM.**—This subject was dealt with in a paper by Mr. G. Parsons. He preferred the White Leghorns, but had also found the Brown Leghorn-Dorking cross good. Fowls should be given plenty of exercise, he said. It was a good plan to throw them heads of wheat to encourage this. Sheds of wood and iron should be provided to protect the birds from the cold, and tick must be guarded against. If possible, he would rear chicks all through the year, and so have hens laying at all times. Otherwise chicks should be hatched in spring. A discussion followed, in which Mr. McCallum said that care should be taken not to overcrowd fowls. They must be well fed, and occasionally receive a meat food. Mr. H. A. Toop favored the incubator, and spoke of the necessity for erecting good sheds and yards for the poultry. Mr. W. Swigden had found fowls profitable; green feed was necessary during the summer. Mr. W. C. Keauschner did not approve of hatching chicks all the year round, but would rear them in the spring if possible. The president deprecated the practice of over-stocking. The hon. secretary and Mr. R. Jasper also took part in the discussion.

**WARCOWIE** (Average annual rainfall, 12.16in.).

**HARVESTING AND MARKETING WHEAT.**—A paper under this heading was read by Mr. T. Ryan. When an area of, say, 300 acres was to be cropped, he would sow 80 or 90 acres with some early variety, preferably Steinwedel or Golden Drop. By the time these 80 or 90 acres of wheat had been reaped and cleaned, the later varieties would be ready for harvesting. He preferred the reaper and winnower to the complete harvester for this district. The former method saved the cocky chaff, which could be used for feed in seasons such as this. He considered it would pay the farmer to put his wheat through the winnower twice. With regard to marketing wheat, he considered it would be very much more profitable to the farmers if they stored their own grain until sold, instead of storing it with merchants. In discussing the paper, opinion was divided as to whether it would pay to run the wheat twice through the winnower. Members generally agreed that it would be more profitable to the farmers to store their own wheat.

**WEPOWIE** (Average annual rainfall, 13in. to 14in.).

November 14th.—Present: six members and one visitor.

**SUMMER FODDER.**—A short paper on this subject was read by the Hon. Secretary (Mr. L. F. Orrock). For the farmer depending on a well for his water supply there was no better summer fodder than lucerne. This should be planted in April or May, on well-worked land, if rain had fallen. There was a danger when spring sowing was adopted of the land becoming too dry before the plant came up. After the first cut stable manure should be spread over the patch, and then harrowed with a weighted harrow. When 12 months old it

was advisable to give it a good dressing of stable manure, which should be ploughed in with a single-furrow plough, using a share with the wing broken off, and cutting a wide furrow. A patch of, say, quarter of an acre would require about 1,000galls. of water per day, and should produce a little more than a ton of fodder every cut. Lucerne should be cut just when commencing to flower. In the absence of facilities for irrigating, sorghum should be sown on any land that was likely to become flooded as the result of heavy rains.

### MIDDLE-NORTH DISTRICT. (PETERSBURG TO FARRELL'S FLAT.)

BURRA (Average annual rainfall, 17.82in.).

November 3rd.—Present: eight members.

THE AGRICULTURAL BUREAU.—The Hon. Secretary (Mr. E. Finch) contributed a paper dealing with the organisation of the Agricultural Bureau. He mentioned that the success of the meetings depended largely upon the chairman and hon. secretary, but enthusiasm and punctuality on the part of members was essential. He advised members to select seasonable topics as the subjects of their papers, and at least one paper should be read at each meeting. All persons interested in the agricultural welfare of the State should belong to a branch. He concluded with a reference to the benefits secured by having water analysed, to ascertain its suitability for irrigation purposes. Suspicious weeds should be identified, and cases of stock illness reported.

MOUNT BRYAN (Average annual rainfall, 15.81in.).

October 31st.—Present: five members.

HAY-MAKING AND STACKING.—Mr. G. L. Nutt contributed a paper. The best time to cut hay, he said, varied according to the kind of wheat to be cut. It was generally considered that when the straw had turned white up to the first node the crop was ready for the binder; but he would cut Le Huguenot just before it reached that stage. This variety should be sown at the rate of 2bush. to the acre, and did best on rich, sticky land. He recommended Waite Tuscan as a good all-round hay wheat, being very fine in the straw and soft. It should be sown early, being rather a late variety. All brown-headed wheats should be cut prior to reaching the stage mentioned. Dart's Imperial was a good hay wheat. Algerian oats made the best hay for horse feed. This should not be cut until the straw was quite purple. Hay cut at the turning stage should be stooked the same day as cut; but if cut while green it should be left in the sun for a day to dry. The sheaves should be stooked on end. The writer then described his method of stack-building. Members generally agreed with the views expressed in the paper.

NORTH BOOBOROWIE (Average annual rainfall, 16.35in.).

August 31.—Present: 16 members and six visitors.

PIG-RAISING.—A paper under this heading was read by Mr. F. E. Waddy. He considered that in this district the keeping of pigs, together with cows, would pay handsomely on farms where lucerne could be grown. The pigs could be either grazed in paddocks and fattened in sties, or, for preference, both methods could be adopted. The sties should be provided with paddocks attached. It was wise to have several paddocks, which could be fed off consecutively. The sties should be well ventilated, and yet draught-proof, as pigs would not readily fatten in the winter if cold. He considered the Berkshire the best of the pure breeds, but for general purposes he recommended mating a Berkshire-Yorkshire cross sow with a Berkshire boar. A breeding sow should be large, roomy, long, broad-shouldered, and short in the snout, and come from a strain known to throw even litters. She should be at least 10 months old before being bred from. She should have plenty of exercise and not be too fat. A week or so before farrowing she should be shut in a sty with good straw bedding (not barley straw) and be given a little bran in the feed each day. The feeding should be regular, and consist of green feed.

of which lucerne was preferable, while clover, barley, peas, and mangolds were also good. A watch should be kept to prevent the mother lying on the young during the first day or so. Continuing, the paper read:—Young pigs grow very quickly. For the first two or three weeks their mother's milk is generally enough, after that they learn to feed, and forage around on their own. If a big yard is available they can run about, and the more independent they become the better they are for weaning. Regularity should be exercised in feeding. If breeding sows are kept, grass and green feed can be used to a great extent, but if pork is required, grain must take a large place in the ration. Of solid foodstuffs barley is perhaps the best, followed by peas, wheat, oats, and maize. These, together with milk, make an ideal food for topping up pigs. Of green foods, lucerne is about the best; clover, barley, peas, and mangolds are all good. We have here land suitable for lucerne, and I believe mangolds can be grown with success, as they do well with water that contains a little salt or magnesia. I tried silver beet last summer, and it did well with the creek water. There are three ways of disposal of the produce from pigs—1, making bacon; 2, rearing pigs for pork; 3, selling young pigs. The trouble with the pig industry in past years has been the sudden fluctuations in the value of the produce, but as more pork is produced and markets are opened up, so the tendency to fluctuate will be overcome. The growth of large bacon pigs or choppers, in my opinion, is not as profitable as the growth of pork and rearing of young pigs. A pig of from 60lbs. to 100lbs., if placed on the market in tiptop condition, will always bring more per lb. than one of from 150lb. to 300lb. in like condition, and it takes more per lb. to top up or grow a large pig. The market for young pigs or slips has been very strong for some time past, and I believe has been the best way of selling. To take advantage of this market, one needs good-quality pigs, as they always sell best. It is very necessary that pigs should be kept in good health, that they may utilise their food to the best advantage. With open paddocks and good clean sties this does not involve much trouble. Charcoal and wood ashes should be always available. Sulphur, limewater, and Epsom salts are good for them in certain cases of illness, but if a pig has a good run of some greenfeed, and a heap of ashes in its paddock, it will rarely need medicine. It is surprising the crop that will grow on a paddock in which pigs have been running. Nearly everyone who has tried this class of stock is confident that they pay: yet the forward movement in their breeding has not come about. I am hopeful that in a few years we shall see many lucerne paddocks, with pigs feeding therein, along Booborowie Plain."

PORT GERMEIN, October 17th.—By permission of the Director of Education the members paid a visit to the Port Germein School to view the secretary's fine collection of specimens. The museum, which covers many years of collecting, consists of specimens from Port Darwin and the North Coast, as well as of South Australia. About 200 bottles are on the shelves. Those most interesting to the farmers were bot flies, bot larvae, horse worms, and tapeworms. Others of interest included, beside a fine collection of Northern Territory shells, buffalo horns, hawk-head turtle, trepang or beche-de-mer, pearl shell, tortoise shell, native weapons, death adder, snakes, lizards, tropical centipede and praying mantis, spiders, and various insects. A four-legged duckling also came in for a fair amount of attention. The hon. secretary (Mr. J. Stewart) chatted with the members on the various subjects, and a very pleasant afternoon was spent.

## LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

BLYTH (Average annual rainfall, 16.46in.).

October 8rd.—Present: 16 members.

HAY CUTTING, STOOKING, AND STACKING.—Mr. J. S. McEwin contributed a paper under this heading. He would not put the binder in the crop until the straw had a dry appearance at the bottom, as hay cut at this period was heavy, and contained

good grain. If the crop contained wild oats, it should be cut before the oats became dry, irrespective of whether the wheat was green or not. Oaten hay should be cut on the ripe side. The straw was then sweetest, and the grain fully matured. Stooking should be commenced within a day of binding. The hay would then keep a good color, and withstand the effect of winds better. He preferred long stooks, four sheaves wide. A space running right through the stooks enabled the hay to dry quickly. The hay could be carted with safety and stacked 12 or 14 days after cutting. He then described the method he adopted in stacking hay.

#### FREELING (Average annual rainfall, 17.85in.).

October 8th.—Present: 13 members.

STACKING HAY.—This subject was dealt with in a lengthy paper by Mr. A. J. Kuhlmann. He drew attention to the waste which was occasioned through carelessness in building stacks, and mentioned that the selection of a suitable site was of the utmost importance. He detailed the method he had adopted, and stated that he had recently sold a stack which did not contain a single damaged sheaf, although it had been exposed to about 3in. of rain from time to time. Another stack had been surrounded three times by about 1ft. of water, and had suffered very little.

GAWLER RIVER.—LICE AND TICK ON SHEEP.—This subject was dealt with in a paper by Stock Inspector Goddard, which was much appreciated by members.

### YORKE PENINSULA DISTRICT.

(TO BUTE.)

#### PINE FOREST (Average annual rainfall, 14.15in.).

October 6th.—Present: 10 members.

SEASONAL CONDITIONS.—In discussing the present condition of the crops one member stated that sandy, hilly soil had given better results than heavy soil in the same paddock, and with the same working, while the best results were in patches where the sand had blown away and left the hard ground bare. Another member mentioned that he worked his fallow dry last season, and it worked up so powdery that he had to discontinue. However, this fallow was producing the best crops at present on his farm. Another had fallowed a paddock and worked it all back, but the hills; these were left owing to drift, and worked after the March rains. At present there was a fair crop on the flats, but none on the top of the hills. The majority of members favored shallow ploughing. Mr. J. Edwards thought it advisable to sow rye for stock feed. A fine plant of German Wonder wheat was tabled by Mr. Edwards. This plant had stooled out 110 stocks from the one grain, and was about 18in. high, not in head, and very healthy.

MAITLAND, November 7th.—A short paper was read by Mr. G. Tossell. He touched on the mode of living of the pioneers of this state, and then stated how farm life could be made comfortable by men who were energetic enough to produce on their own holdings commodities for their own use. A short discussion followed.

MINLATON, 5th November.—Mr. R. C. Page, in a short paper, pointed out the advantage of always keeping a few handy tools on the farm. This enabled the farmer in many instances to effect his own repairs.

A paper having reference to the womenfolk on the farm was then read by Mr. R. H. McKenzie. He mentioned in eulogistic terms the part they played in keeping the farm in a prosperous condition. Both papers were discussed by members.

MOONTA, October 7th.—The meeting was held at the homestead of Mr. J. Atkinson. Fruit trees, vines, flowers, &c., were doing well, and an even crop of 380 acres of Yandilla King was considered by members to be the best they had seen this season. Members were entertained at tea by Mrs. and Miss Atkinson.

## WESTERN DISTRICT.

COORABIE (Average annual rainfall, 11in. to 12in.).

August 1st.—Present: 17 members and five visitors.

**BREAKING IN FARM HORSES.**—Mr. E. J. Oats read a paper on this subject. He said:—"The importance of properly training horses for work on the farm is not sufficiently realised. Many horses that have turned out 'wrong-'uns' or jibbers have been made that way by careless or cruel treatment during the schooling or breaking-in period, in which case it is the farmer and not the horse who is entirely to blame. The making or the spoiling of the horse commences when it is a foal. I do not agree with handling farm horses from birth. Very often petting results in making the horse tricky and cunning, and continual petting will make some horses so quiet that they are too slow and sleepy. If young foals have to be handled for any reason, such as castrating or drenching, get the operation performed quickly, and release the animal. I do not mean let the animal go out into an almost bare paddock to starve. Supplement the natural feed with good, wholesome chaff, sufficient to keep the foal in good growing condition. When feeding the foal in the stable, behave kindly but firmly towards it, and right from the outset show that you are master and must be obeyed. Do not, however, throw sticks or stones at it. At the time of castrating, it is advisable to take a couple of joints off the end of the tail—the hair will not become so knotted or unsightly later on. With early foals a suitable time to start breaking in is about hay time, when the foal is two years old, provided that the animal is well grown. If it is backward, it is far better not to think of working it until the following seeding. Haycarting is, in my opinion, very suitable work; it is not too heavy, and it entails a lot of starting and stopping, which is an essential part of a young horse's education. Of course, before a horse can be put into a wagon team, it has to be handled, and the method I advise is something like the following:—Get the animal into a substantial closed-in pen (say, about 20ft. x 10ft.) by itself. With a light stick, about 10ft. long, stand in the doorway, and keeping the colt well back from you, gently rub him over with the stick. You will soon find that you can rub any part of the animal. He may kick at first when you touch him between the legs or under the belly; if so, don't tease him, but rub him again in some less touchy spot. The idea is to let the colt know that you are not going to hurt him. Having got the colt accustomed to this treatment, the next move is to procure a headstall and a piece of rope of handy size, about 20ft. long. Make a running noose in the rope, and lasso the animal, or place the noose over the head with the aid of the stick. Keep his head towards you, and very quietly and gradually work your way up to him. Give yourself plenty of time. Beware of striking, and if the animal has a tendency to do this, obtain another light stick, about 7ft. or 8ft. long, and with it stroke him about the nose and neck, until you find you can with safety get up to his head. Now get the headstall on, and fasten the throat strap. Fasten a large bit securely on the off side of the headstall. Get the bit into the colt's mouth, and make the final adjustment on the near side. Get a rope similar to the first-mentioned, but about 25ft. long (the same rope will do if the colt is fairly quiet). Run one end through the near side bit ring from inside, inside the throat strap, over the head and down inside the throat strap, and through the off-side bit ring from outside, and tie fairly close behind the jaw. Pull him about a bit to teach him that he is securely caught; then, provided you have strength enough to securely hold him, he may be let out of the pen into the open, or, better still, if your pen opens out into a good yard. Here hunt him around until he realises that he cannot get away. If he rears, immediately slacken the rope—that is, if you are behind him, or you may pull him right over, which is dangerous. The next step is to take the animal out on to a piece of open ground, clear of stones, stumps, &c., and circle or lunge him, first in one direction, then in the other. A little of this exercise and you will be able to approach and get up to him easily, when a little petting may be allowed. The next thing is to teach him to stand over. Stand near the hindquarters with a little whip in your hand, and pull his head towards you, to get him to turn round short. A flick of the whip will move him, and as soon as he moves give his head a quick pull. By repeating these tactics a few times on both sides, he will soon

learn what is expected of him, and the benefit of this lesson will be very apparent later on. This exercise satisfactorily completed, the next is to teach him to lead. The main thing in this part of the colt's education is to overcome his natural fear of man, and here it is well to gently pet and fondle him, particularly about the head and neck. Do not stand directly in front of the colt, but rather a little to one side, and occasionally flick him behind the fore-legs with the whip, to induce him to step forward, which directly he does, give his head a pull towards you. Coax him by gentle handling about the head. Continue patiently with this treatment for a little while, and the lesson is soon learned. When the colt will lead satisfactorily it is well to give him a rest—in fact, this is sufficient for the first day. The next day it is possible, as a rule, to catch the colt easily. Fasten the rope, and see that he has not forgotten to lead. Now fasten a rope on each bit ring long enough to enable you to hold the ends and stand behind him clear of his heels. Drive him around and about, teaching him to turn to the off or near side at will. It is well when doing this to let one or other of the reins hang low, to touch the colt about the legs and breech, tending to overcome touchiness. The time is now ripe to start work. I suggested haycarting. Yoke five steady horses to the wagon, leaving the near-side body vacant for the colt. Attach a pair of body chains to drawbar, and hang a spider on the near-side shaft. Select a well-fitting collar and hames (preferably second hand), and put them and a pair of winkers on the colt, and bring him quietly around to his place. It is necessary to have someone to assist in putting on the spider, but there is not usually much trouble in getting yoked up, and off for a load. So long as the colt will walk along in the team it is sufficient for a start; let him come to the collar of his own accord, if he will. If he seems disinclined to pull, try taking the winkers off while travelling with the load. Provided the colt is not exerting himself too much it will not hurt him to stay in the team all day, so long as the work is only hay-carting; but be careful not to give him too much on any account. These hints can only be accepted as a guide, as all the methods must be adapted to the temperament of the animal you are handling, and it is well known that horses vary very much in this respect. The majority of the views expressed by the writer were agreed to by members. In answer to questions and criticism, Mr. Oats said he did not approve of tying the head up for mouthing; he would prefer to leave the bit in the colt's mouth all night, if necessary. To teach a colt not to pull back he advised tying to a good tree, with a stout rope, and hobbling the animal. He further added that in breaking in the colt the lessons must be followed up regularly, and not neglected, and then resumed, say, a week or two afterwards. To cure pulling back, Mr. Hanson suggested putting a sound branbag round the animal's neck, and fastening it very securely with a stout rope or chain to something that could not possibly be moved or broken; then encourage the horse to try to pull away a few times, and it would soon give up all attempts at so doing. Mr. Muegge did not approve of docking. Members emphasized the value of teaching young horses to come to the whip. A horse that had properly learned this lesson would always face the catcher, rather than turn its heels towards him.

#### MITCHELL.

October 3rd.—Present: 14 members and five visitors.

**SEED WHEAT.**—This subject was dealt with in a paper by Mr. H. Voumard. He advised farmers to grow their own seed wheat, which should be perfectly ripe before being harvested. The seed should be placed loose in a stone barn, with a wooden floor, where it would not be so likely to suffer damage from mice as if placed in bags. Seed wheat should be graded, and if it showed any signs of smut, should be pickled about two weeks before seeding time. This would give it time to thoroughly dry before being sown. He considered one bushel of graded wheat to the acre sufficient if sown after rain, but if sown in dry weather a little more than a bushel per acre would be required to allow for a certain portion not germinating. He favored Thew, Firebank, American No. 8, and Genoa for either grain or hay, all of which were fairly good rust-resisting varieties. In discussing the paper Mr. D. Sampson stated that he had found that stone barns harbored weevils. Mr. Jenkins considered three-quarters of a bushel of seed wheat to the acre sufficient for this district. The varieties favored by members generally were Jacobs, Marshall's No. 3, and Federation.

**FARM BUILDINGS.**—Mr. G. Wright read a paper under this heading. He contended that it was best to have as many buildings as conveniently possible under the one roof. The amount of water caught was also increased. The stable, chaff-house, engine and chaffcutter shed should all be attached, and although there was a danger of fire, he considered the convenience would warrant the barn and implement shed being placed under the same roof. He preferred stone walls of about 14in. thick. The stable should be long enough to allow 6ft. space for each animal, and be about 15ft. wide, to leave room for a passage behind the mangers for feeding. The doors should face the east, and the floor be wood-blocked or concreted. The size of the chaffhouse would, of course, be determined by the number of stock kept, but it was wise to have it a little larger than was really necessary at the time. The size of the barn and implement shed, &c., would likewise be governed by what was required of them. When building, provision should always be made for any possible future additions. He preferred galvanized iron roofs. Such buildings as the blacksmith's shop, pigsty, fowlhouse, and cowshed, should be separate, and a short distance from the others. He gave in detail his ideas of the laying out of farm buildings. Members discussed the paper, and generally agreed with the views of the writer. Mr. Jenkins would not have the floors of the stables concreted, as this would necessitate the expense of having the horses shod.

#### ROBERTS AND VERRAN.

November 3rd.—Present: 12 members and one visitor.

**HAYMAKING.**—This subject was dealt with in a paper by Mr. W. Sharman (Hon. Secretary). He considered it advisable at the present time to cut as much hay as possible. Wheat hay should be cut when the grain was passing from the milky stage; that was about three weeks after blooming. Oats should be cut on the ripe side. Hay to be fed long should be cut a little earlier than that to be chaffed. He would build round stooks of 25 sheaves close behind the binder, as this would give a good color and good corn. The stack should be 18ft. wide at the bottom, and have round corners, and be built with butts outwards. In the roof the outside sheaves should be placed butts outwards and the inner ones heads out. The roof should not be built too high, and on no account should the stack rest on the ground. In discussing the paper, Mr. F. Masters stated that he would mix the oats and wheat hay together in the stack. Salt sprinkled on the hay while being stacked would improve it. He favored stacking in a shed, but if in the open the stack should be well covered with straw. Mr. J. C. McCallum also took part.

**MANGALO, September 12th.**—Mr. W. E. Waters read a paper, in which he pointed out to members that to be successful the farmer should always provide for the future, especially in respect to fodder and water.

**MILTALIE, August 29th.**—**VERMIN ON EYRE'S PENINSULA.**—Mr. P. G. Wilson contributed a paper, in which he made a strong plea for concerted action in connection with the destruction of wild dogs, foxes, and rabbits in this district. A proposal has been made, he said, to secure foxes, and liberate these in the neighborhood of Port Lincoln, with the idea of exterminating the rabbits; but he strongly deprecated the idea as one likely to be productive of more harm than good. He thought payment should be made for the scalps of foxes, which would encourage landholders to give more attention to their destruction. The majority of members were opposed to the introduction of foxes to Eyre's Peninsula.

**YALLUNDA, October 3rd.**—A paper, setting out the advantages of mixed farming, was read by Mr. J. S. Perry. A discussion followed, Messrs. Forrest, Olston, and G. Teakle taking part.

**YALLUNDA, October 31.**—In initiating a discussion on hay, the Chairman (Mr. Fairbrother) mentioned the fact that this district would cut sufficient for local requirements this season. Mr. Cabot stated that the Dart's Improved was a good hay wheat. Mr. Allen had cut nearly 3 tons to the acre from 10 acres of Algerian Oats. Wheat crops generally were higher than the oats this season.

## EASTERN DISTRICT.

## (EAST OF MOUNT LOFTY RANGES.)

COOMANDOOK (Average annual rainfall, 18.0lin.).

September 25th.—Present: 25 members.

**MALLEE FARMING.**—Mr. J. Guy read a paper in which he dealt with the financial position, over the first five years, of a farmer taking up a virgin mallee section under the "Crown Lands Act," which provided that the farm could be held free of rent for that term. He took the hypothetical case of a selector with a capital of £300, and emphasized the importance of especial care in connection with the purchase of implements. The return from a crop following a scrub burn he estimated at 5bush. per acre, that on ploughed land at 7bush., and for stubble 13bush. to 14bush. Seeding would be at the rate of 50lbs., 50lbs., and 60lbs. per acre, and manurial dressing 70lbs., 80lbs., and 100lbs. respectively. The initial expenses for the first year's crop would amount to £467 1s., and the return from 220 acres would equal £140. The second year's expenses were set down at £210 10s., and the return from 200 acres burnt scrub and 80 acres ploughed stubble £215. The third year's outgoings totalled £121, and the returns from 120 acres fallow, 130 acres of ploughed stubble, and 150 acres of burnt scrub £375. By the fourth year the implements and machinery should have been paid for, and expenses would be reduced to £80. The value of the crop from 160 acres fallow, 100 ploughed stubble, and 150 acres burnt scrub should amount to £388 10s. The fifth year's cropping would consist of 250 acres fallow, 150 acres ploughed stubble, and 150 acres burnt scrub, yielding a value of £700. The outlay for the five years was thus £1,058, and the return £1,749 15s. For the period named he did not think sheep could be profitably kept on the holding. Mr. R. Upton, sen., thought sheep were an advantage after the first year or two, as they would keep shoots and other rubbish down.

## CRESSY (NOW MINDARIE).

October 12th.—Present: eight members and two visitors.

**SHOEING HORSES.**—Mr. E. L. Parker read a paper on this subject. Horses well shod, he said, were much easier to keep in good condition than those left unshod, and were also able to get through more work. He had found that in the mallee country the stumps were very severe on the unshod hoofs. Owing to the unevenness of the ground the animal's weight was often thrown on portion of the hoof only, and if unshod it was therefore likely to break away. Hoofs were at their softest during and just after winter, and were then apt to bruise, just as they were likely to break away during hot dry weather. For draughts he favored the wide shoe of about  $1\frac{1}{4}$ in. by about  $\frac{3}{4}$ in. thick. The extra width of the shoe would protect the feet from the sharp ends left on the broom and other bushes after a burn. For light horses he recommended a shoe  $\frac{7}{8}$ in. wide by  $\frac{3}{4}$ in. Care should be taken to see that the feet are evenly trimmed and present a level bed to take the shoe. As the frog of the foot was intended to take the jarring, it should not be cut more than was absolutely necessary. The hoof should not be burnt too much, as this operation dried up to a certain extent the natural oil and tended to encourage cracking. The front shoes should be well hollowed out, and so press chiefly on the outside of the hoof. The nails should be placed well towards the toe, where they should be driven highest, the height gradually being reduced as the quarters were approached. They should be driven well home, but not drawn up too tightly into the hoof. The shoe should never press on the heel, as this caused lameness. Care should be taken when clinching not to file away under the nails too much, as there would then be a danger of breaking them when bending. The hoof should in no case be filed away above the nails. The shoes should be large enough, with plenty of width at the heels, in order not to cause contraction. He considered five to six weeks long enough to keep the shoes on. Members then discussed the paper.

GERANIUM (Average annual rainfall, 16in. to 17in.).

October 3rd.—Present: 20 members.

**LIVESTOCK ON THE FARM.**—Dealing with this subject in a paper, Mr. R. C. Jacobs said the chief argument in favor of the practice of marketing the

produce of the farm "on the hoof" was the necessity for maintaining and improving the fertility of the soil. A very small percentage of the substances essential to soil fertility, and consequently plant growth, he said, was retained by animals fed thereon. Under the conditions existing in this district, sheep would be found the most suitable livestock to carry on the farm. Pigs, cattle, and even poultry would be found useful in their places. With regard to the first-mentioned, quality, conformation, and early maturity were points requiring strictest attention. That stock of this class, if systematically managed, paid handsomely in conjunction with wheatgrowing, had been proved beyond dispute. Overstocking should be avoided, and a reserve of fodder, either in the form of hay or ensilage, should always be available. For early feed, there was the choice of barley, rye, mustard, rape, &c. Self-sown wheat on the fallow, or land left out, would supply winter feed; oats and peas should provide feed in spring, and the summer months could be gone through on a late crop of peas and sorghum, lucerne, millet, and the stubbles. Those crops which of themselves tended to improve the land, i.e., legumes, oats, and rape, should receive every attention. It was most economical to feed off in comparatively small paddocks. Mr. Norton supported the opinions of the writer of the paper.

#### GLENCOPE (Annual average rainfall, 33.84in.).

September 5th.—Present: nine members.

**CLEARING AND CROPPING MALLEE LAND.**—In introducing a discussion on this subject, the Hon. Secretary (Mr. H. S. Cope) said:—"In estimating the cost of clearing the land of mallee stumps there are many points indirectly related that are overlooked by many farmers. It is my desire to prove that the cheapest method is to roll down the mallee, and after the burn to cultivate the light, sandy soils with a stump-jump implement, and to plough shallow (say, 3in.) any clay or heavy land. This means that the first year's crop is cheaply put in, and a much lower yield is more profitable than subsequent crops on this land, where fire-raking, shoot-cutting, and ploughing the whole has to be done. Therefore, it is more profitable to grow one crop only on the new land, then on the second year to plough the land fairly deeply for fallow, and instead of setting the plough to jump the stumps, to put on a couple of extra horses, and pull all the stumps possible. These stumps have to be taken from the land before we can obtain the return the land is capable of producing. By pulling them out at first we almost do away with the cutting of shoots, and we have the winter months in which to pick and cart off the stumps; this enables the land to be worked on the fallow system from the second year of cultivation. The system of taking off three successive crops necessitates two years of shoot-cutting and fire-raking, and in most cases the stumps pulled up have to be carted off after the seed is sown. The ploughing, seeding, shoot-cutting, and clearing of stumps all have to be done at seeding time. By allowing the stumps to remain in the ground at least one-third of every acre so cropped is non-productive, owing to the space thereby covered. In addition, a vast amount of moisture is necessary to sustain several tons of mallee shoots per acre. We are losing about 40 acres in every 100 we sow, which means, on a 9bush. crop on stumpy land (say 100 acres), 300 bags; whereas, on the same area, free from stumps, the yield would be 500 bags. To cultivate on the three successive seasons, each year pulling as few stumps as possible, must be debited first with the cost of the fire rake, ploughing, shoot-cutting, and stump-picking; then the loss of two-fifths of two seasons' crops; or the cost of seeding, cultivating, clearing, and super. for one-third of the area sown, for no actual return. The cost of these alone more than covers the cost of fallowing the smaller area, viz., two-thirds. Three crops grown under the alternate wheat and fallow system must give a much better result than the usual pioneer system of three crops in succession. Hence the increase per acre must be credited to the cost of ploughing the stumps out. The same applies to the cost of ploughing, sowing, and harvesting, together with two-fifths of the cost of seed and super. Without any actual increase of yield the increase works out (for one crop) at 13s. 6d. per acre; but if, as experience has proved, once cleared of stumps, the yield of the land is more than doubled, it actually means two seasons' crops will return more wheat than three successive crops. In other words, we

produce more wheat in two crops on a given area under these conditions than three crops by the tickling process; we also save one season's seed wheat, super., cultivating, seeding, and harvesting." Mr. C. H. Evans said, as a result of his experience, that land free of mallee stumps yielded double the return secured from similar land not so cleared. Mr. Colbert agreed. Members were convinced that the practice of allowing mallee stumps to remain in the land for several years of cropping was costly and unprofitable, especially in dry seasons.

#### HALIDON.

October 7th.—Present: 14 members and two visitors.

**LUCERNE-GROWING.**—Mr. W. F. D. Clark (Hon. Secretary) read a paper. Every settler who possessed a bore and well, he said, should have a lucerne patch. He emphasized the feeding qualities of this fodder for cattle, horses on light work, sheep, pigs, and poultry. It would thrive on either light or heavy soil. The land should be well cleared and be covered with stable manure, worked as deeply as possible, the surface being then worked down to a fine tilth; it should then be flooded. The seed should be broadcasted at the rate of 20lbs. per acre, and then lightly covered with a rake or by dragging bushes over the ground. About 3in. of water per month would be necessary, and he would flood the land and then not water again until absolutely necessary. Lucerne was a perennial plant, and should last from six to 10 years. Hunter River was the best variety, but it was difficult to obtain this seed true to type. Province and Turkistan were also good. Lucerne in its early stages was susceptible to frosts, and should therefore not be sown until after the frosts had passed. A good stand would yield about 10 cuts during the summer, averaging about 3 tons per acre at each cut. In discussing the subject, Mr. Harris stated that he had a crop which did well during the summer, but it was afterwards killed off by frosts. He recommended mulching the lucerne at the beginning of the winter to guard against this. Mr. Von Doussa had had eight cuts from his crop last year, and it was still flourishing, despite the winter. In reply to a question as to whether lucerne would thrive without irrigation on some of the sand rises in the district, Mr. Clark replied that it depended entirely on the rainfall.

#### KINGSTON-ON-MURRAY.

November 6th.—Present: 17 members and eight visitors.

**ORCHARD MANURING.**—A paper was contributed by the Hon. Secretary of Berri Agricultural Bureau (Mr. W. R. Lewis). It was useless, he said, to expect the same land to produce crops year after year without the help of soil fertilizers. He recommended drilling in 2cwts. per acre of superphosphates and sowing with either peas, tares, or vetches. When the crops reached the flowering stage they should be ploughed in. In September or October the soil should be given a dressing of 2cwts. of bonedust, bone super., or blood manure and 1cwt. of nitrate of potash per acre. The application of fertilisers to heavy or stiff soil had a better effect if from 1 to 2 tons of gypsum was first worked into the soil. He instanced cases where gardens which had ceased to be profitable had been restored to perfect health, and had produced heavy crops, after being systematically dressed with manures. He recommended the use of any matter that was likely to decay easily and quickly. This would supply humus to the soil. As an experiment last year he had used a mixed fertiliser of 200lbs. bone super., 150lbs. sulphate of potash, and 75lbs. sulphate of ammonia per acre, and had made a profit, after paying for the manure, of £8 per acre on currants and £3 1s. 2d. per acre on Sultanias. Messrs. Holmes and Wetherall mentioned that wood ashes had a beneficial effect on vines and orange trees.

#### LAMEBOO (Average annual rainfall, 16.55in.).

October 3rd.—Present: 17 members.

**LUCERNE.**—Mr. Campbell read a paper on this subject. The following is extracted therefrom:—"Given equal favorable opportunities, I think that it is generally admitted that there is no crop that will give a better return to the farmer or grazier than a well-cultivated lucerne crop. I am quite satisfied that with a reasonable amount of labor, and care, that our own district will yet make a name for

itself as a fodder-growing district, comparable to most ordinary lands in the State. The land which I have tried has consisted of poor, sandy soil, and also a red soil on top of limestone, but the lighter soil proved the better, owing to the fact that in this the plant could get its roots down much deeper. There is hardly any part of this district that is unsuitable for its cultivation, particularly the looser soils. The red flats will be found too hard until they are made more friable; then they will be quite as good, if not better, than the other. The way to attain the desired friability is to plough in green stuff, manure, or anything that will make humus. I would not advise going in for large areas to start with. About an acre in close proximity to the windmill, so that one can resort to irrigation in the dry weather, is sufficient. It will be necessary to have the land clear of all stumps so that it can be ploughed deeply, as it is essential to have the surface nice and loose. Scatter a good coating of stable manure over the ground, and then plough it in. It may then be advisable to go over the land, either with a cultivator, or with the harrows. The time for sowing, I should think, would be about August for this district. It is also advisable to drill or broadcast a light sowing of barley to protect the young plants from the frosts. After the barley has been cut for green feed, the lucerne will come on quickly. It is best to cut the crop, for even if one exercises great care in feeding, it will not grow so fast as when it is cut. It is advisable at the end of the winter, just as the plants are beginning to show signs of growth, to go over the crop with the harrows, after giving it a dressing of artificial or stable manure. Some advise using the disc cultivator in place of the harrows, but of this I have not had any experience, and would advise caution in that respect, as there is a danger of cutting out too many of the plants. The best time to start cutting is when the plant is starting to flower, but this of course can be regulated to requirements, as it does not necessarily follow that the younger plants are not good for stock. If for haymaking, then it is necessary to cut the crop at just the right time, for if it is too young there is the danger of it drying too quickly, and thereby losing a large proportion by the leaves falling during the gathering-in operation. I have had five cuts in a year, but on favorable soils more than this can be taken off. I did not have any facilities for irrigation, but, judging from the plants in close proximity to the fruit trees, which I watered, the return would have been wonderful if I could have irrigated generally. If dairying is one of the resources of the farm—and it certainly ought to form one—then the results can be considerably increased by a fair supply of green lucerne as part of the daily ration. My milch cows were fed on lucerne and straw, which had been sprinkled with molasses when stacked, and the result was most satisfactory."

#### LONG FLAT.

November 2nd.—Present: 14 members and two visitors.

**FODDER FOR DAIRY CATTLE.**—Mr. P. Opie read a paper under this heading. After 10 years' experience on swamp lands, he had come to the conclusion that the best fodders for dairy cows were lucerne, *Panicum crus galli*, prairie grass, and Italian rye grass mixed with *Paspalum dilatatum*, maize, and mangolds. Lucerne took pride of place. This fodder could be fed green in the summer and as dry hay in the winter. It was invaluable in times of drought. Then came *Panicum crus galli*. This should be sown in early September, and could be grazed, cut, or fed to cattle. *Paspalum dilatatum* could be fed to save lucerne if it was desired to stack the lucerne for winter feeding. In December he would sow maize, and in early autumn prairie grass and Italian rye grass should be sown mixed. This would ensure a grazing paddock for the winter months, and with half an acre of mangolds and the dry lucerne hay, would carry the dairyman right through the winter. He recommended "Hunter River" variety, which should be grown from South Australian seed. An interesting discussion followed. Mr. Rouse stated that he had had splendid results from imported lucerne seed, which produced a plant of better foliage and finer stem than the local seed. In reply to a question, Mr. Opie stated that he had tested both local and imported seed, and found that the locally grown seed produced a healthier plant with a quicker growth, being 6 in. taller than the plants from the imported seed. Mr. Liebelt's experience differed from this. Mr. Mann considered that in respect to cutting and raking lucerne hay a great deal depended on the weather.

**MOEGAN (Average annual rainfall, 9.29in.).**

October 31st.—Present: seven members.

**RABBIT DESTRUCTION.**—Mr. O. Hausler read a short paper under this heading. Trapping rabbits for market could be made a profitable undertaking, he said, but he recommended poison for destroying them in large quantities, where the skins were wanted for sale. Wheat, soaked in water, with a quantity of strychnine added, and then placed in small heaps along the edges of growing crops, would be found effective. Members considered that now a dry season was on it would be more easy to destroy the pest, and every landholder should use the poison cart during the coming summer.

**CONSERVATION OF FODDER.**—The Hon. Secretary (Mr. C. A. R. Wohling) dealt with this subject in a short paper. He emphasized the necessity for conserving during good seasons everything that might serve as feed for stock in periods of drought. Stock that was being fed on straw should, if possible, be turned into a paddock containing some green bush, saltbush for preference, occasionally. This would lessen the danger of worms. He advised farmers not to overstock their paddocks in good seasons. In discussing the paper members generally considered that after this drought had passed farmers would pay more attention in good seasons to providing feed for their stock in possible future bad years.

**PARILLA (Average annual rainfall, 16in. to 17in.).**

October 29th.—Present: 13 members and one visitor.

Mr. M. Shannon read a short paper entitled "Remarks on the Season." The prospects in this district were a little better than those in some of the others, he said. Early light rains and thunderstorms had given the crops a start, but they had gone off considerably. Up to the present feed had been fairly plentiful, but the outlook for the summer was rather poor. This district was very fortunate in having a good water supply. Stock were in good condition, and with early rains next year none should be lost. Farmers should benefit from lessons taught by the drought. Members discussed the paper. Messrs. A. J. Stevens and J. Lee both remarked how well the feed was holding out in this district, and how well the grain (what little there was) was filling out. Mr. J. A. Darley said that on well-worked portions of his paddock the grain had filled out better than it did last year. Messrs. P. W. Lewis, W. Rush, and C. Millstead also took part; they considered this district admirably suited for wheatgrowing.

**RENMARK (Average annual rainfall, 10.93in.).**

September 3.—Present: 11 members and four visitors.

**SUMMER FODDERS.**—Mr. H. S. Taylor read a lengthy paper on this subject. The following is extracted therefrom:—"At a time like the present, when a drought makes certain a shortage of chaff, with consequent high prices, the thoughts of irrigationists naturally turn to the growing of summer fodders. Those who have good lucerne patches will find them of inestimable value. Those who have not must make good the lack as best they may. If no unoccupied land is available for cropping, the centres of vine rows or of young trees may be utilised with advantage. For feeding green, few summer fodders can compare with maize, where horses are in question. In America—both north and south—maize is grown extensively for the corn, which is largely used in fattening all kinds of stock. In parts of South America, especially, maize corn constitutes the only food of the horse other than natural grasses. In Australia maize is grown principally for dairying purposes. But even in this connection its value is not sufficiently recognised. It has this advantage over the sorghums and millets, that it can be fed with perfect safety at any stage of growth. Except in the early stages of growth it should be chaffed for horses, unless one has cows or pigs to eat up the refuse. A cow will eat a good big stalk, whereas a horse will trim off the leaves, take the top of the stalk, and generally leave the bulk, and better part of it. Pigs will chew it to the last shred. In my own experience a hand chaff-cutter was found of great value when feeding maize to horses. Until matured, the stems cut easily, and mixed with wheaten chaff, make a good working feed. As with all fodders of this class, the plant attains its highest feeding value at near maturity. The disadvantages of maize, considered as a horse fodder, are that it yields only one cut, dies off rapidly after maturity, and does not make good hay. A success of sowings will, however, provide a supply of succulent feed throughout the whole of the summer, and the stover, as the dry stalks are called, is by no

means without value as food. Sowings may be begun as soon as the danger from frost is past, and continued till the New Year. With regard to the feeding value of stover, or the dry maize stalks, the *Farmer and Fruitgrowers' Guide* (published by the New South Wales Department of Agriculture) states that it is used at the Hawkesbury Agricultural College with considerable success. At Hawkesbury the stalks are put through the McCormick husker and shredder, and, so treated, are found valuable for the farm brood mares, colts, fillies, and dry stock, which are kept thereby in good condition throughout the winter. The tested food value of shredded maize is given as in the ratio of three tons of shredded corn to one ton of clover or Timothy hay. Maize requires a rich soil for its proper development, but a comparatively poor soil may be made productive by heavy dressings of animal droppings. The best crop of maize I ever saw, was grown on land that gave very poor returns until liberally dressed with cow manure. Proper cultivation is even of more importance than manure. Maize should be sown in drills, a yard apart, and not too close in the rows, whether intended for green fodder or for the cobs. When it is grown on a large scale an implement known as a check planter is used. This drops three or four seeds at the intersection of every yard, allowing for the cultivation of the crop in two directions. For ordinary purposes the simplest way is to open up a furrow and drop the seed in it by hand, or by means of a hand planter. The soil should be thoroughly worked before sowing, and kept well cultivated—but not deeply—afterwards. In South Africa maize silage is used very freely for horses. It is there considered very desirable to chaff the silage before feeding, and horses at first do not commonly "take" to it. It is regarded as a splendid horsefeed, but requires to be fed with care, or indigestion and flatulent colic will result. Chaff and bran may with advantage be fed with the silage, which has very fattening properties. Mouldy silage should on no account be fed to horses. Among the varieties most favored for fodder are Red Hogan, Yellow Dent, Hickory King, Flat Red and Yellow Mornya. The last-named appears to be a very free grower, crops of this variety in Victoria have yielded over 55 tons of green feed to the acre. Red flat has yielded over 40 tons to the acre." Mr. Angove stated that irrigation blockholders in Victoria were sowing oats at the beginning of September. Mr. Agars mentioned that English barley sown in January at Mildura had produced good crops; personally he favored maize as a summer fodder. Mr. Waters had been very successful with *Paspalum dilatatum*.

**BERRI, October 31st.**—The production of meat on small irrigated blocks was discussed. Mr. Stochling favored raising pigs and poultry, and advised the growth of lucerne as a primary fodder. Kaffir corn, barley, and peas should also be fed. For topping up pigs, grain or pollard was necessary. Mr. Lewis instanced a case where a farmer near this district had fed 60 sheep from one acre of lucerne for eight weeks past, and would probably continue to do so right through the summer.

**BORRIKA, October 31st.**—In a discussion on hay-making, Mr. Brown remarked that he had seen very good hay made of rye mixed with wheat. Mr. Miell did not favor rye for hay. He considered Huguenot the best hay wheat, while Mr. Jones favored Baroota Wonder, and Mr. Collins preferred Baroota Wonder and White Tuscan. Messrs. Brown and E. H. Huxtable reported that the frost had damaged a crop of Marshall's No. 8 on his farm. Mr. Seary had seen part of a crop cut badly by frost, while another part which had been set back, through being eaten by rabbits, was not affected.

**NETHERTON, November 4th.**—In the afternoon the Poultry Expert (Mr. D. F. Laurie) gave a practical demonstration. He dissected a cockerel, and explained to the members present the uses of the various organs and also their disease and treatment. In the evening this same officer gave an interesting lecture on poultry matters generally.

**PARILLA WELL, October 8th.**—Mr. E. Johnston recommended growing fodders for summer feed on fallow land. Mr. A. Inkster agreed. Mr. J. S. Ferguson considered it unwise to grow such fodders on the fallow if it were intended to sow that land with wheat. This gentleman's remarks were indorsed by Mr. F. A. Webster, who considered that if the farmer wished to have good wheat crops he must keep his fallow clean.

PINNAROO, October 2nd.—An interesting and instructive demonstration and paper, dealing with oxygen, hydrogen, and water, were delivered by Mr. E. H. Parsons, A.S.A.S.M. He dealt with a number of chemical principles, and conducted a number of explanatory experiments.

WAIKERIE, November 2nd.—The condition of the season's fruit crop was reported on. Currants, sultanas, and gordos were showing splendid yields, apricots were light, peaches fair, oranges light to good, while mandarins were very good.

## SOUTH AND HILLS DISTRICT.

CHERRY GARDENS (Average annual rainfall, 35.03in.).

November 3rd.—Present: 13 members.

HORSE-SHOING.—This subject was dealt with in a paper by Mr. Henry Jacobs. At the outset, he said, it was important to see that the shoe properly fitted the foot. In preparing the foot, it should be rasped down level on the outer edge, the inner sole being pared out a little if required, so that the shoe would not bear on the inside at all. The frog should not be interfered with, except to cut off any ragged ends, neither should the bone running from the heel to the frog be weakened. The shoe should be made hot enough to work, and have the nail holes cleaned out with a pritchell and a clip turned up in the centre of the toe. It should be made perfectly level before being placed on the foot. It was not necessary to have the shoe red hot when it was being fitted on. It was a good plan after fitting, especially the front feet, to ease them a little on the heel. Nailing on should be commenced on the right-hand side of the foot, a light claw hammer being used. Each nail should be screwed off as driven, about  $\frac{1}{4}$  in. being allowed for clinching. The nails should then be drawn up by placing the pincers on the screwed-off ends and hammering their heads. Before clinching it was necessary to rasp under each nail so that it could be hammered well down into the hoof. The pincers should then be held on the head of each nail in succession while the end was turned and clenched with the hammer. Finally the clenched ends should be smoothed down with the rasp. It was unnecessary and harmful to pass the rasp over the whole of the outside wall of the foot. Members, in discussing the paper, generally deprecated the practice of excessive rasping of the hoofs, and of placing on the shoes while red hot. Mr. G. Hicks stated that this latter practice sometimes resulted in bad feet and lameness.

CLARENDON (Average annual rainfall, 33.67in.).

September 28th.—Present: 15 members.

FODDER CROPS.—In a paper on this subject, Mr. A. Phelps said that to enable dairying and lamb-raising to be successfully carried on on the small holdings of this district it was necessary to supplement the natural pastures with forage crops. Lucerne was the best available, but, as with sorghum, maize, mangolds, and chou moellier, it could only be grown in small areas on the flats. For early feed, rye could be grown, which could well be followed by barley. For feeding off, rape would give the best return. With this, as with other crops, careful cultivation of the land was essential. It was best sown in spring, about 4lbs. of seed being drilled per acre. If broadcast, 5lbs. of seed, with  $\frac{1}{4}$  cwt. of super, should be put on to the acre. It should then be top-dressed with a sprinkling of sulphate of ammonia. Sheep should not be put on to the crop when hungry, nor should they be allowed to remain thereon for more than two hours before they become used to the feed. They should be run in an adjoining grass paddock, with access to rocksalt. Mr. J. Spencer then read a paper. He considered lucerne the best fodder. It was excellent for butter production, and would cause no taint if allowed to wilt before being fed to the cows. Mangolds should be grown by every farmer, he said. They constituted an excellent tonic for stock during dry weather, were good milk-producers, and very suitable for pigs. Maize and sorghum could well be sown immediately after potato crops were dug in this district. For autumn sowing King's Early Red wheat grew rapidly, and stood up better than oats and barley.

**GUMERACHA** (Average annual rainfall, 33.30in.)

October 31st.—Present: 11 members and three visitors.

**FARM MANAGEMENT.**—Mr. A. Moore contributed a paper. He suggested that on account of the high prices ruling for meat, dairymen should cease the practice of killing their calves and instead rear them by hand and fatten them for market. They could be fed on separator milk with boiled linseed added. Wells should be cleaned out, and perhaps deepened to catch all the water possible. He preferred deepening by means of a drill. With regard to ploughing the orchards, he considered this should be done this year as early as possible, as the trees needed all the moisture available. As the subsoil was not moist this season, the soil should be kept worked up right through the summer. On account of the poor outlook of the hay crop farmers should make every possible effort to provide sufficient food for their stock, for much hand-feeding would have to be done owing to the shortness of the grass. In September last year he had sown Algerian oats on some land which had not been broken up for 30 years, and had cut 1 ton of hay to the acre from it. There were many summer fodders which might be grown to help over the difficulty. Mangolds constituted a good root crop, which yielded heavily; and which, with potatoes, could be fed to either cattle or pigs. To help owners of starving stock, he urged farmers in this district to take in as many head as possible, and at a reasonable price. Members discussed the paper at some length. The majority were opposed to the idea of fattening calves for market, as they considered this practice unprofitable. They would only rear the best heifers for replenishing the milking herd. The points touching on summer fodders, conservation of water, and working the orchards were all agreed with.

**HARTLEY** (Average annual rainfall, 15in. to 16in.).

September 30th.—Present: 18 members.

**ROAD-MAKING.**—A paper on this subject was contributed by Mr. W. Bermingham, who was of the opinion that the crowns of the roads were made too high. For a 12-ft. wide road 3in. was sufficiently high for the crown. All holes should be attended to as soon as possible. When renovating a road the old metal should be picked up before the new metal was put down to ensure a good binding. If rolling in the wet weather a good weight should be placed on the roller, but if in dry weather this was unnecessary. Members generally agreed, and considered it unwise to mix hard and soft stone together.

**SHEEP ON THE FARM.**—This matter was dealt with in a short paper by Mr. D. Clark. He favored a type bred from the Lincoln-Merino cross ewe mated with either a Lincoln or Shropshire ram. The lambs always commanded a good market price, and were quick maturing. When the lambs were taken away from the ewes early the mothers benefitted, and would cut a good fleece, and also have a chance of getting in good condition before the grass died off. He had found the gross profits on wool from crossbred ewes to exceed that from Merinos. A good discussion followed, most members agreeing that the cross mentioned in the paper produced a good lamb for market, but did not think there was more profit in the wool from the crossbred ewe than from the Merino. Some members considered that only 50 crossbreds could be carried where it was possible to carry 70 Merinos.

**THE FLY.**—Mr. A. Stein read a paper under this heading. He urged upon members the necessity for destroying wherever possible this disease-spreading insect. Manure heaps, rubbish tips, &c., were its favored breeding places. He referred members to the article on this subject, appearing on page 319 of the October, 1913 issue of *The Journal of Agriculture*. In the discussion which followed, members generally agreed with the writer of the paper.

**NARRUNG** (Annual average rainfall, 17in. to 18in.).

November 7th.—Present: 16 members.

**HAYMAKING.**—Mr. F. Baker contributed a paper on this subject. For hay, he said, wheat should be cut soon after the bloom had fallen, but oats should be left until the kernel had hardened and was going brown. He preferred Cape oats, as they could be cut earlier than other varieties without danger of their being bitter. They should be placed in round stooks of 20 to 30 sheaves as soon as cut, and could be left a fortnight or more, according to the weather, before being carted. He would not move the stooks after rain, as, if properly put together, the hay would dry better as it was. The writer then described his method of stack building.

## PORT ELIJOT (Average annual rainfall, 20.33in.).

September 19th.—Present 11 members.

**CATTLE BREEDING.**—A paper dealing with this subject was read by Mr. H. B. Welch. The present was the time, he considered, for those who possessed good grazing paddocks to secure cattle of as pure breed as possible for breeding purposes. He would advise the small farmer to purchase one or two more milking Shorthorns or Jerseys. Farmers with large holdings should procure some purebred Herefords or Shorthorns to breed stock suitable for sending on to stations. "In-breeding" should be avoided, as this produced bad doers. He had bred Herefords for 27 years from pure stock, and had found sufficient recompense in the fattening qualities of the stock to warrant the expense of procuring the services of pedigree bulls. The demand for good young bulls for station purposes warranted the breeding of pure stock, and would pay the persevering breeder, owing to the increase of the beef export trade. Rather than each individual farmer keeping an inferior animal, he thought it a wiser plan for them to co-operate in purchasing a pure-bred bull. This animal could be looked after by one man, and any of the others who required its services should pay a small amount of, say, 5s. He deprecated the practice of allowing a bull to run at large with the herd. An interesting discussion followed.

## STRATHALBYN (Average annual rainfall, 19.28in.).

September 29.—Present: 22 members.

**TREATMENT OF SKINS AND HIDES.**—The subject was dealt with in a paper by Mr. J. P. Raggat, who also gave a practical demonstration in folding skins. The paper read as follows:—It is estimated that the loss to the State through careless treatment of sheepskins alone amounts to about £30,000 annually. Each year our hide and skin products are increasing in value. Oversea markets demand the best of goods, and only sound skins can be sent as first quality. All damaged, whether the injury is small or great, come within the category of second-rate goods; hence the reason for exercising great care if the producer desires to secure the full value of the pelt. In taking the skin from the sheep's back very little knife should be used, it is far better to take it off by pulls and punches, and thus reduce cutting the pelt to a minimum. When the skin is removed, as soon as possible hang it lengthwise across a rail or pole, always being careful to see that the shanks or edges of the skin do not turn up, as this would provide a splendid ground for maggots or weevil. If the skins are taken from sheep found dead, they require more prompt care on account of the increased quantity of blood found on the skin. These skins should never be mixed with the first quality, as no matter how much care is exercised, they are only second raters. During summer months, skins should not be dried in the sun, as the heat injures the pelt, and in many cases completely destroys it, and thus the farmer loses from 1s. to 1s. 6d. in the value. It is best to dry them under cover during the whole year. Some men use drying frames, but I advocate the plain rail, as the pelts are often spoilt by being stretched. The natural weight of the skin is sufficient to keep it in shape. When preparing for market fold the skin with the woolly side out. Remove the trotters, as these are nearly always used as a convenient means of moving the bundles about. Fold the skin with a crease right down the centre of the back, and fold the head again, right over the shoulder; never fold the head part first, as that portion of the skin, being the last to dry, if placed inside, is liable to sweat and damage the portion in contact with it. It is essential, before packing, to paint the skin with a wash to guard against the ravages of weevil. This is absolutely necessary during the months from October to April. Never use salt in preserving a sheepskin, for by so doing one practically takes away its export value. A good dressing is made from arsenic 2½lbs., washing soda crystals 2½lbs., add 5galls. of water, and boil for three hours; keep it well stirred. Add to this sufficient water to make 16galls. For a few skins it would be sufficient to make a small quantity in the same proportions. Great care needs to be exercised in preparing or using this paint, as it is poison, and should not be allowed to enter cuts or wounds on the hands. I would suggest that a skin should be hung up for 12 hours, then spread on the floor while being painted so that the wash gets into all the edges and parts where weevil are likely to gather. After it has been lying on the floor for an hour replace it on the rail. In handling hides and calfskins it is much better to leave a patch of flesh on than

to put a niche in the skin. It should be salted as soon as possible. From 12lbs. to 15lbs. of salt is necessary to place the hide in good condition. It should be spread out perfectly flat. The salt should be sprinkled on thickly, care being taken to cover the whole, more particularly the edges and meaty parts. In folding, one should be careful to bring the outer edges in line along the centre of the back, and then fold again; then turn the head back and also the tail to meet it, and fold again. To preserve a rabbit skin pull it over a piece of stout fencing wire bent to the shape of a bullock bow. Always see that the skin is stretched on the wire with one side of the bow along the centre of the back, thus keeping the tail on top. By this means little fur is exposed, and a well-shaped skin is the result. This should be treated with a wash before being sent to market.

#### URAILDA AND SUMMERTOWN (Average annual rainfall, 44.35in.).

September 7th.—Present: 14 members.

**VEGETABLE SEED.**—This subject was dealt with in a paper by Mr. C. Oliver. Whilst it might be found that potatoes grown on high land one year and the seed saved and sown in swamp land next season would prove satisfactory, he said, it would be unwise to continue this practice for many years without a change of seed. As a general rule he recommended purchasing potato seed from the Mount Gambier district or from Melbourne. For land not under irrigation he preferred the Pinkeye. For irrigated land he favored the Carmen, Up-to-date, Redskin, Snow flake, Prolific, and Pinkeye varieties. The stumps of cabbages should be transplanted in good soil, as more seed was produced by the stumps than by the full plants. Good, brown, oval onions should be transplanted for seed. After the seed had been cut the onions should be put aside, as they would seed the second year. Carrots and parsnips should be selected for seed when the crop was being prepared for market, and likewise transplanted, so also, should turnips. Seeds of such vegetables as beetroot, lettuce, radish, leeks, parsley, &c., should be purchased from the seedsman. It was important that all seeds should be perfectly dry before they were gathered. In the subsequent discussion Mr. R. M. Cobblestick considered that vegetables transplanted and irrigated would produce good seed, particularly parsnips and carrots, which should be staked. Onions for seed should be planted early. Care should be taken to see that the soil was free from slugs.

#### URAILDA AND SUMMERTOWN (Average annual rainfall, 44.35in.).

October 5th.—Present: 13 members.

**SIDE LINES FOR GARDENERS.**—Mr. H. G. Dyer contributed a paper. In some seasons, he said, the crop of some particular product was so large and the price so low that it did not pay to market it, and almost all of it was consequently, at times, left to rot in the soil. He therefore recommended gardeners to keep a few pigs, which could be given this surplus produce as part of their food. Dairying in a small way might also be carried on in conjunction with the gardening, any waste, such as separator milk, being fed to the pigs. Poultry could also be kept to advantage. Mr. J. C. Oliver agreed with the paper, but Mr. Collett did not hold with having any side lines along with gardening.

**BLACKWOOD, October 19th.**—Mr. E. Ashby gave an interesting address on the "Flower Garden," and illustrated his remarks with specimens.

**HARTLEY, October 28th.**—Mr. G. Hill read a short paper in which he urged members to pay more attention to their homesteads, implements, &c. He also desired that the meetings be attended more punctually and regularly, and that the question-box be placed on the table at each meeting.

**INMAN VALLEY, October 28th.**—Rabbit destruction was dealt with in a paper by Mr. G. McCoy. Properties should be wire netted and then the rabbits could more easily be destroyed, he said. One method was to fumigate the burrows with carbon bisulphide and cover them with a piece of wire netting and earth. A piece of rag, soaked in a tablespoonful of the sulphide, placed just inside the burrow and set alight would prove effective. Mr. Rose preferred a dirty piece of wool to rag, as it was longer burning. He would stop up the burrows with old manure bags. Mr. Jagger had seen sheets of newspaper placed over the burrows with good results. Mr. Dennis had used phosphorized pollard, and found that it was readily eaten by the vermin.

**IRONBANK, October 31st.**—In reply to a question as to the best method of cultivation for asparagus, and the best variety to plant, Mr. R. Coates advised breaking the ground to a depth of 2½ft., and planting to a depth of 6in. He advocated sprinkling salt on the surface of the ground, and dressing the land with heavy applications of manure. He considered "Colossal Purple Dutch Erfurt Giant" the best variety.

**LONGWOOD, October 31st.**—The meeting was held at the homestead of Mr. Furniss. Members made an inspection, and were very interested in the orchard, which showed signs of very good cultivation. The fruit trees were very healthy, although much of the apple blossom had withered owing to the frosts, dry weather, and hot winds. Pears were doing fairly well, apricots were very good, while cherries and plums were poor. Some fine pines came in for comment, some of which, nine years old, had increased 5in. and 6in. in girth during one year.

**MACGILLIVRAY, November 3rd.**—Mr. A. J. Nicholls read a short paper advising members to sow fodders in February or early in March to provide feed for the coming year. He recommended rape as good for cattle or sheep, and Cape barley, rye, and oats for horses. Oats and rye would stand a good deal of feeding off if put in early, but Cape barley was the fastest grower. Rye would do better than either barley or oats on poor land. He would sow rape at the rate of 5lbs. or 6lbs. per acre; rye, 1bush; barley, 1½bush.; oats, 2bush., with 1cwt. of mineral super. in each instance. Mr. Wheaton had obtained best results from Cape barley. Rape should be put in early, 4lbs. per acre on poor land being sufficient. Mr. Williams advised members to put in some lucerne.

**MEADOWS, October 6th.**—Present: 16 members and four visitors.—**BREEDING AND FEEDING POULTRY.**—Mr. E. F. Stevens, of the Mount Barker Branch, read a paper on the subject. [Mr. Stevens's views on the subject have already been published on page 1223, of June, 1914, issue.—Ed.] In reply to questions Mr. Stevens said White Leghorns did better in a warm district; the heavier classes of birds were more suited to this locality.

**MILANG, October 13th.**—During the afternoon the Government Veterinary Lecturer (Mr. F. E. Place) gave a practical demonstration on the horse, explaining the functions of the various organs, causes and effects of various ailments, and their remedies. In the evening this officer gave an interesting address on the "Treatment of Mares in Foal," impressing on members that in the event of any trouble first-aid treatment was invaluable.

**MORPHETT VALE, October 20th.**—Mr. Pocock read a paper in which he advised members to make some early provision for sowing green feed, as soon as a fall of rain was experienced. He thought it advisable to sow some sorghum or maize on portion of the fallow, sandy loamy soil being the best. A few early wheats could be sown on some of the stubble land, either for cutting early for green feed, cutting for hay, or for feeding off. He recommended King's Early or Gluyas, which, if they were to be fed off, should have some barley or oats sown with them. Rye was also recommended as a good green feed, which stood the dry weather very well.

**MOUNT BARKER, October 21st.**—The meeting was held at the homestead of Messrs. Pope Bros. Mr. Henshaw Jackson (the Wool Expert) gave a practical demonstration in handling the fleece and wool-classing.

**PORT ELLIOT, October 17th.**—Members discussed some of the papers which were read at the annual Conference in September last. Mr. Hamilton Welch stated that barley, sown early on land which had last year been sown with peas, had come up with the first rains, and proved very profitable. He had put sheep on it, and had also fattened on it cattle that had been in poor condition, in six weeks. Mr. J. Brown suggested planting swedes for summer feed, but Mr. Hargreave stated that this should only be done in very moist soil, or where irrigation was practised.

## SOUTH-EAST DISTRICT.

## WIRREGA.

October 3rd.—Present: eight members and visitors.

**EFFECTS OF LIME ON SOILS.**—Mr. H. H. Exton contributed the following interesting paper on this subject:—Lime decomposes the dormant mineral plant food in soils, and thus renders available for the plant phosphoric acid and potash which otherwise would remain inert. It acts on the vegetable organic matter in the soil, and converts part of it into nitrogen compounds, available for the plant. It is very effective in sweetening sour land, and thus renders more free from disease crops grown on such soil; it especially improves the quality of the herbage. It enables crops to make the best use of superphosphate, dissolved bones, sulphate of ammonia, and other soluble manufactured chemical manures, preventing any excess of acids in such manures from exercising an injurious effect on the crop. The physical action of lime is no less important. It is difficult to exaggerate the improvement that lime effects on the dryness and workability of strong soils, which, in many cases, would not be fit for cultivation had they not been treated with lime, and on lighter soils—the sands and gravels—it exerts a good effect by forming a weak cementing agent, and increasing the cohesion of the particles. Heavy soils become more porous, better aerated, warmer, and less difficult for the root of the plant to penetrate. The caking to which such soils are liable in dry seasons is prevented to a great extent. The surface of the soil is rendered more friable, and lends itself to better tillage. Light soils are rendered more compact. The application of lime in moderate quantities to the soil assists the beneficial process always going on in the fertile soils, due to the activity of bacteria, thus helping the conversion of ammonia and other compounds containing nitrogen derived from decaying organic matter and nitrogenous fertilizers into nitrates, the form in which plants mainly if not entirely utilise nitrogen, and also the fixation of the nitrogen from the atmosphere by leguminous plants. In sour soils these processes are at a standstill. Lime quickens all the processes of plant vitality, and enables the crop to assimilate more nitrogen, phosphate of lime, and potash. It is essential therefore that the soil should be kept well supplied with these plant foods, otherwise it will become unproductive. If we could get lime as the farmer in New Zealand can, almost rail carriage free, there is no doubt it would be a great factor in settling a great deal of what we might call the Wirrega class of country. I see that the older settled parts of this district are getting overrun with sorrel, thus showing that the soil is very sour. Even in our land here it is showing very strong in patches.

**MOUNT GAMBIER, October 10.**—**TRUCKING STOCK.**—Members generally agreed that it was unwise to truck stock for market directly after they had received a heavy feed, as they generally became very dirty in the trucks, and as a result their value was depreciated. This trouble was not so noticeable, however, when the feed was dry.

**SANDALWOOD, October 10th.**—The Chairman (Mr. Willoughby) read a paper dealing with poultry on the farm.

**WIRREGA, August 8th.**—A paper was read by Mr. Langdon, in which he described the method of fencing which he adopted.

## INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

### STOCK INQUIRIES.

Replies Supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S.,  
Veterinary Lecturer.

"W.R.C.," Farrell's Flat, states that with many farmers cocky chaff, raked straw, and similar fodder will have to be main rations for working horses and dairy cows, and that fears that stoppage will result are entertained. He asks—What should be added, and what are the real merits of molasses, molasses meals, and copra cake, and which is best for dairy cows?

Reply:—A fairly bulky book would be required to give an answer to these very natural questions. Various oil engines are made to work on heavy oils and gasolines; they run all right in the show-ground on the heavy oils, but on the farm, loaded up without expert care, they clog and kick and jib unless the gasolines are used. So the horse engine, running light without work in the paddock manages very well on the coarser fodders, but when in work requires the more easily digestible. Both in the case of the engine and the horse the engine is running and consuming fuel, but in the one case it can be stopped and the cover put on, in the other consumption still goes on, and energy is expended in extracting from the fodder the nutriment necessary to keep the works of digestion, respiration, circulation and so forth going. Now, in the case of weather-beaten straw, the energy necessary for this is greater than the energy derived from the food. On the other hand the horse engine requires a certain amount of coarse fuel, crude fibre, to assist in the digestion of the concentrated fuel, say oats, otherwise up go his heels and the engine races. Details of this may be studied in those valuable bulletins on "Wheaten Hay," Nos. 73 and 82, copies of which have been forwarded. Cocky chaff

on analysis contains both coarse and fine food constituents—more of the latter than straw—and is undoubtedly a very valuable food. But the digestive engine has to work hard to get the fine from the coarse, so that it does not follow that if a horse is doing well on 10lbs. of cocky chaff that he will do double as well on 20lbs. He will not, for his digestive organs will have more than double work to do and gain less than double benefit. His big bowels, where most of this work is done, will get blocked up, so that the best thing to add to the cocky chaff would be good hay. This being out of the question, oats may be used with advantage, and probably weight for weight the best addition would be a pound or two a day of split peas or peameal. This would be a far cheaper feed than bran under present conditions, and provide the necessary energy to enable the horse to extract most benefit from the chaff. Spices, such as salt or pepper, are much valued in countries where only dry innutritious fodder is available. In good seasons here they are not so necessary, but will undoubtedly help the digestion of cocky chaff and straw. A hot bran mash on Saturday night will also help, and in many ways will be beneficial; bran is a very dear food, but an equally cheap medicine. Molasses has a certain fattening value, but if fed at over 5 per cent. of the weight of other foods given retards their digestion and undoes the good which is certainly derived from the use of small quantities. This good, however, is probably derived more from its spicy flavor than actual food value. It thus assists digestion and has a slight laxative action which is very useful when coarse fodders are the only feed. Its main disadvantage in summer is that it attracts such enormous numbers of flies. It is much cheaper to buy it in the long run than to get molasses meals, which are mostly absorbent indigestible fibre, such as crushed sugar cane, sawdust, or peat fibre. Indigestible fibre of this sort can be obtained much more cheaply at home from cocky chaff and straw, and it is of a better quality and will soak up molasses just as well as they will; moreover, one has not so much to pay for the labor of mixing, and there is a saving of freight. Copra cake is a very valuable feed when of good quality, but a horse gets as much fat as he needs out of oats, so the value of cake to him is more in the way of a spicy addition to his feed and the slightly laxative effect of the oil. Most horses, however, will show a decided improvement in sheen of coat and plumpness if they get  $\frac{1}{4}$ lb. to  $\frac{1}{2}$ lb. of cake a day. Thus it is specially useful under the circumstances now under consideration. For dairy cattle it has other values, and is to be recommended before molasses; they extract both fats and proteins from it in large quantities and use them up in making milk, both quantity and quality. They will take 4lbs. to 7lbs. a day and give a profit on it, but

the quantity must be lessened as soon as a cow begins to lay on fat: this is wanted in the udder, not on the rump, unless the butcher is going to have her. Horses, as a rule, will take a wineglassful or more of raw linseed oil in chaff if brought on to it gradually, and its laxative effect is useful.

"Farmer" has a mare suffering from sores under both eyes. He has been applying Condry's fluid and mixture olive and eucalyptus oils. He seeks advice.

Reply:—The sores are due to parasites brought by flies, so the first step is preventive, a fly net or fringe. The treatment by Condry and mixed oils is good, but better results will ensue from lightly touching the sores once a day with caustic (nitrate of silver); this had better be done in the evening, and the oil applied in the morning.

"H.S.," Port Lincoln, asks treatment for horses suffering from flatulent colic. He treated one horse, which, however, died.

Reply:—See pages 238-9, October "Journal of Agriculture," Vol. IV., 1911-12, for treatment. The danger in this sort of colic is the immense distension of the abdominal organs, leading to interference with the heart's action, and vigorous rubbing of the flanks in addition to the back raking is most advisable. A drench that seldom fails to give relief is  $\frac{1}{2}$  a pint of gin with a good nobbler of peppermint, or better, about 30 drops of peppermint essence with a little warm water, or half a teaspoonful of ordinary cloudy ammonia in a little cold water, either repeated in half an hour if necessary. A good emergency remedy is a tablespoonful of mustard, mixed as for the table, put on the tongue. In drenching, the head should only be held high enough to give a slight fall on the back of the tongue, and the mouth of the bottle should tickle the roof of the mouth, as the sensation of swallowing begins there. The treatment suggested in the letter was all right, and would have succeeded in many cases, but some deaths must be expected, and in this case the horse was ill for some hours before being seen.

"A.J." asks advice concerning cow which is weak across the loins, poor, but not starving, and has difficulty in rising. Left side of stomach is hard. The cow is in milk.

Reply:—The symptoms of impaction paralysis, otherwise nerve failure, because the energy required to extract nutriment from food is greater than the energy derivable from the food. Chances of recovery are not good, but if she is dosed with gruel, and a pint of yeast two or three times a day, and morning and evening 1 dram powdered *nux.vomica* and 1 dram sulphate of iron and 1 dram saltpetre are

added to the gruel for a few days improvement may follow. One dram of the above is equivalent to a flat teaspoonful.

"E.K.," Willowie, asks treatment for horses when overgorged with doughy wheat.

Reply:—Grain in the ear will seriously upset a horse's digestion, and laminitis ensues, the animal dies of poisons eliminated in the system. Treatment—Drench with a quart of milk mixed with  $\frac{1}{4}$  lb. baking soda, and repeat in a few hours or next day if necessary.

"A.W.," Coomandook, requires treatment for five-year-old mare which, when in prime condition, was ridden 70 miles in a day and a half, became tender-footed, so was shod in front and ridden 25 miles home, where she arrived quite knocked up. Now lame all over, and lies down most of the time, when she stands up is all of a tremble; improving a little.

Reply:—The symptoms of laminitis, induced by unaccustomed work and possibly by hot shoes on worn feet. Treatment—Off with the shoes, cold swabs to the feet, to be followed, as recovery sets in, by Stockholm tar and tallow (equal parts) rubbed into walls and soles daily. Give an ounce of Epsom salts in food three times a day for a week or so; green food or bran and rest for three months.

"T.D.," Nantawarra, has mare eight years old which in some way got her hip down. He asks how to put it right.

Reply:—There are two conditions generally spoken of as hip down. One arises from injury, such as rushing through a door, and means that the haunch bone, or exterior angle of the ilium, is displaced, the result being that the quarter droops and the muscles on the top of it waste. Lameness does not ensue, and treatment is useless. The second condition, shown by difficulty in getting the leg forward and wasting of all the muscles of the quarter, arises from the pubic bones at the bottom of the pelvis not coming into exact apposition after foaling. The condition continues till the next foaling again relaxes the pubic ligament, and the bones resume their proper place. In this case also no treatment is of any use, but it is well to get the mare in foal as soon as possible.

"W.C." asks (1) What is the treatment for cows suffering from what is known as "cripples"? and (2) If cows can be dosed with lime to make up deficiency in fodder?

Reply:—(1) The name "cripples," like "crankum," "droppers," and many others of a like nature, covers many disorders, but generally refers to a condition when there is lameness behind with swelling of the stifle joint, which cracks or rattles on movement. These symptoms are sometimes due to tuberculosis of the joint, but not often in South

Australia; sometimes to rheumatic inflammation of the joint, fairly common in swampy country; sometimes to scurvy, due to insufficient nutriment, not necessarily shortness of food, but want of variety. This last is fairly common in South Australia, and is sometimes recognised as a precursor of "dry bible," especially when the fetlocks are affected. A layman can differentiate the three conditions, because there will be other symptoms, such as cough and wasting, in tuberculosis; the lameness will shift from joint to joint in rheumatism, and be more painful than in scurvy. Drastic local treatment, such as firing and blistering, is usually applied in either of the three conditions, and strong liniments containing oil of origanum are much relied on. Whatever is used, nature is the healer. (2) Dosing with lime is a very poor substitute for sufficiency of that substance in fodder; however, it is sometimes recommended in the form of limewater, prepared by putting a lump of quicklime as big as an egg into 2galls. of rain-water, leaving for 48 hours, and straining; a pint or a quart is given daily with food. Another way is to give bonemeal licks, consisting of sweet bonemeal, and allowing 3ozs. to 4ozs. per cow daily. These licks are sometimes made by adding sulphate of iron, saltpetre, or sulphur in the proportions of three or four parts of bone meal to one of the other constituents. The animals either lick it from a box or a dose is mixed with feed. The quantity for heifer or cow would be about the same, as it has no particular medicinal property, and any excess taken would not be absorbed to the detriment of the animal.

"J.H.P.," Morphett Vale, asks treatment for horse, six years old, which has gone stiff all over, is very hidebound, holds his head out, and his eyes turn back, showing bloodshot whites, legs sprawl out, feeds and drinks well; has been doing heavy carting.

Reply:—The symptoms are very suggestive of lockjaw (tetanus), and it would be advisable to summon qualified veterinary aid without delay. In the meantime, if there is any external wound, cleanse it with a strong antiseptic, keep the horse apart and quiet, give green or sloppy food, and get him to take as much Epsom salts with it as he will up to 8ozs. a day.

"D.R." has stallion which was sanded. He gave the horse a drench of raw linseed oil, and fed on bran, pollard, and oaten chaff, with a condition powder twice a day; the animal passed sand for a week. About the third day it was noticed that his penis was hanging out, the next day it was swollen. It got worse, was lanced, and bled freely; then dressed with swabs of carbolic solution 1/40; there was an improvement, but the testicles became swollen. The swelling pits, and an oily substance exudes on to the bandages. The penis is now being bandaged with linen soaked with embrocation.

Reply:—The condition is known as paraphymosis, and probably the condition powders contained saltpetre and resin, with other stimulating drugs, and then flies stung the protruding organ, and the swelling prevented its return; unfortunately this often results in paralysis, and inability to withdraw the organ; the carbolic treatment was better than the embrocation. It will be advisable to throw the animal and foment well with hot water containing laudanum, about an ounce to the pint; then return the penis into the sheath, after oiling well with olive oil, and, if necessary, take a stitch or two through the end of the sheath to keep it in place, and sling with a bran bag, including the testicles in the sling; their condition is only secondary to the other. Give 15 drops of strong tinct. camphor three times a day on the tongue for a week, and there will be some hope of a recovery.

“D.C.,” Port Broughton, asks treatment for mare which, when suckling a six-weeks foal, suddenly became stiff in the forequarters, with a swelling along the belly to the udder. The bowels are open, and she frequently makes attempts to pass urine.

Reply:—The symptoms are those generally attributed to influenza, but caused really by upset to the constitution by the growth and development of microscopic worms in the circulation. No alarm need be felt on account of the swelling, the inconvenience of which causes the attempts at urination; it is nature’s way of side-tracking the poisons which the kidneys cannot deal with. Treatment:—Twice daily a teaspoonful of saltpetre and a teaspoonful of sulphate of quinine; if these are not readily taken in a little bran they may be mixed with a little molasses and put on the tongue. In less than a week the symptoms will have subsided, and then a tablespoonful of sulphur may be given once a day in the food as an alterative.

“J. B. N.” has horse which was seized with severe pains in the loins or behind the short ribs; it has been ill about 10 days, is off feed, paws the ground, lies down, and then sits up like a cat and looks at flank; is not bound up, but does not pass water freely. Previous to this attack the horse was fed on damp hay.

Reply:—Damp hay has caused the trouble, which is in stomach and colon, and the symptoms are not very favorable for a recovery. Treatment:—Give half a pint of castor oil and 25 drops of strong tr. camphor, with 25 drops ess. peppermint; repeat the two last every three hours, if necessary, and the castor oil in 24 hours, if necessary. Veterinary chlorodyne may be given instead of the camphor and peppermint, if preferred.

"E.H.," Port Broughton, asks advice concerning (1) horses with sore feet, which stamp and rub as if standing in bed of ants; there is a breaking out about the hoofs which is like greasy heels. (2) Horse which when at work scours badly and has gone stiff in all legs.

Reply:—(1) The symptoms are caused by minute parasites. Treatment—Give a tablespoonful of sulphur in food once daily for 10 days; mix benzine one part, raw linseed oil five parts, and dress the heels and legs with it every evening till relieved. (2) Subacute laminitis, following some acute digestive trouble. Treatment—Keep at light work, feed on bran mash only for two days, then stop work and give half-pint of castor oil. Follow this twice daily for a fortnight by 10 drops of tr. nux vomica.

"H.S.C.," Purnong, asks treatment for horse suffering from bad greasy heels; they were treated and dried off, but the horse now staggers or wobbles, holding head close to the ground.

Reply:—The greasy heels were nature's attempt to throw off poisons from the system; these accumulating produce the semi-paralytic symptoms described. Give bran mash only for two days then a 6 dram aloes ball; and when this has ceased to scour, give 10 drops of tr. nux vomica twice a day for a week. A change to green feed is very desirable.

"Nigger," Waikerie, had a horse which was on rough, dry scrub feed. It got down and was shot. Post mortem showed four tumors in stomach, 1½ in. to 2 in. across. Matter was squeezed from this, and cells were found to be filled with tiny worms. There were also fair number of white worms, 2 in. long, and reddish worms, 1 in. long, in paunches. The horse was getting arsenic daily in its food.

Reply:—The horse would probably have rallied on good food, but it would have been a matter of cost of food against value of horse. The tumors described in the stomach are caused by a worm called *Habronema muscae*, which spends its larval condition in flies, and is inoculated into the horse by them. In South Australia more than 10 per cent. of horse efficiency is lost on this account. Prevention—Reduce number of flies as much as possible; they breed in undisturbed horsedung. Treatment—A teaspoonful of baking soda in food twice daily. The other worms were bloodworms, *Sclerostomum equinum* and *Tetracanthum*, for which the arsenic is a good remedy.

"E.G.C.," Tailm Bend, seeks treatment for a horse suffering from injury to one of its eyes; the eye appears to be gradually wasting away or sinking in at the corner, water and matter continually coming from it.

Reply :—The symptoms are those of an injury in the nature of a prick, say, from barbed wire, or of acute ophthalmia, probably the latter; in either case the sight will most probably be lost. A cloth should be hung loosely over the eye, tied to the forehead band and cheekstrap of the bridle; the cloth should be kept damp with a lotion made of a pint of water, a pint of methylated spirit, and an ounce of tr. calendula. If after a fortnight of this treatment there is an improvement, a little dry boracic acid may be blown into the eye once or twice a week. Treatment will, however, not be very satisfactory.

“F.B.,” Auburn, has a stallion which has a deep crack in near front hoof. He seeks advice.

Reply :—It would be best to put the animal under the treatment of a qualified veterinary surgeon, but if this is not possible, a local anaesthetic such as cocaine should be injected, then the crack should be pared to the quick, and the foot treated with antiseptic fomentations till healing commences, when the crack should be plugged with beeswax, or, better, plasticine; the head of the crack should be fired V-shaped, and a blister applied to the coronet; as the horse is a heavy one, it will be better shod; but all bearing must be taken off the bottom of the crack for an inch on either side. It may be necessary to clamp the crack with special clamps.

“J.T.C.” asks what should have been treatment for sow which farrowed, would not eat or drink for two days, and then died. Post mortem showed udder very hard indeed; organs apparently healthy, but body very hot soon after death.

Reply :—The sow died of parturient fever. Preventive treatment would have been 10 drops of tr. pulsatilla once a day for a week before farrowing; this could have been given in a little milk before feeding, and would have been readily drunk. The condition of the udder emphasises the physiological fact that most of the milk is produced by the gland as the young are sucking. Ordinarily an ounce or two of Epsom salts given once a week for a month before farrowing is good treatment.

“C.D.,” Belalie North, had trouble with four of his horses. One, a dray horse, used to lie down, puff up, and groan, and his sides were hard. Two doses of linseed oil failed to relieve, and he died. The post mortem showed dung very hard. Another, a mare with a foal at foot, is dull, and mopes, off appetite, and stands about; the dung is fair. The third, a riding pony, is restless in the yard, keeps on lying down, and looks at flank, but seems bright about the head. The fourth is a cart horse, which does not seem in much pain, but

he lies out flat for a while, then gets up and tries to eat a little; he is getting weak, and is always flapping upper lip. The inquirer states:—"We are feeding on half straw and half real good hay chaff, but they do not drink very much. Do you think the straw did it?"

Reply:—Straw and new hay have brought on impaction colic; the symptoms are very well described in your four cases; the flapping of the lip indicates liver complications. Treatment—Get the bowels open by giving twice a day 10 drops of tr. nux vomica, and twice a day tr. bryonia, 10 drops; these can be put on the tongue with a little molasses or sugar; give them for a week or so. Stop off at least half the feed, and substitute a pound or two of crushed oats, a pound or two of bran, and a handful of boiled wheat two or three times a day. Rub the flanks well for 10 minutes morning and evening, and get them to drink more by putting an ounce or two of salt in the feed once a day. Water before feeding, and give reasonable exercise.

"F.T.W.," Boothby, had a filly which fell away in condition, and was treated for blood worms with Fowler's solution, apparently without result. Having read of splendid result from use of vinegar as sand remedy, gave half a pint. Next day the filly died. Later made post mortem; result, all organs apparently healthy, no sand, a few blood worms, large intestines covered with scores of cysts, opaque, and containing fluid. He forwards some of cysts and asks are they hydatids?

Reply:—The good results attributed to vinegar for sand are due to fermentation, which can be more readily established and more safely by milk and honey or yeast. The bodies received are not hydatids, which are watery cysts, but mesenteric lymphatic glands, which ordinarily a layman would not notice in their healthy condition; but these have become enlarged and degenerate, on account of containing embryonic worms, sclerostomes, only visible under the microscope. They eliminate poisons which produce symptoms of loss of condition and general muscular weakness, often resulting in paralysis; but in this case it is interesting to note that many of them were dead on account of the arsenic treatment. But for the vinegar episode the filly would have had a good chance of recovery.

"R.W.C.," Petersburg, has cows with very sore teats, which are difficult to heal; boracic ointment and mercurial ointment was used without success. The sores begin as a little red pimple, spread in a circle, and heal in the centre, and seem to be very catching.

Reply:—The symptoms of cow pox, which is very catching; so affected cows should only be handled after healthy ones, and the hands carefully disinfected after touching them. Boracic ointment generally effects a cure, but if not, try carbolic soap; and if this does not answer, an ointment of tr. rhus. tox. 1dr., vaseline 1oz. Give the cows a tablespoonful of sulphur in the food daily, both as curative and preventive; those that are badly affected should also have a flat teaspoonful of tartar emetic in the food, once daily for a few days.

“McG.” had cow which became weak and staggering, the tongue was hanging out, and she was constantly dribbling. The animal died, and post mortem was made, with the result that, except gall bladder was very full, nothing unusual was found.

Reply:—The onset of so-called dry bible, really scurvy, although cow in good condition. Prevention—A lick of sweet bone meal 4 parts, saltpetre 1 part. Treatment—Probably useless, but 1 dram of powdered nux vomica in a pint of yeast once or twice daily might have helped.

### HORTICULTURE.

“R.S.F.,” Port Lincoln, sends specimen of beetle which is doing great damage to fruit trees. He asks for remedy.

Mr. G. Quinn, Horticultural Instructor, replies:—“The beetles are the so-called ‘cureulio’ (*Otiorrhynchus cricicollis*). It has been dealt with effectively on young non-bearing trees by spraying with arsenate of lead, 1lb. in 8galls. of water. At Coonawarra, S.E., it has been prevented from injuring the fruiting trees by yarding fowls in the apple orchards, and by placing tin rings around the tree stems—some use a simple ring like an inverted funnel, with the bottom edge standing away from the stem and fastened close at the upper end to prevent the beetles crawling under it. Others make a more effective trap by bending a strip of tin—piece of kerosene tin—around to make a shallow trough, which is joined with putty. Into this trough a little machinery oil is poured every few days, so as to keep it moist. The beetles cannot cross the oil, and if they dip their legs into it and get out again they invariably perish. The troughs needs cleaning of dirt and dead beetles about once each week, when they may be given a little fresh oil. Around Adelaide these beetles usually slacken their attacks after December, but it is not always so in all localities, as at Coonawarra they persist into the apple season (March and April). This band and trough system is used over very much larger orchards at Coonawarra than three acres.”

## ROSEWORTHY AGRICULTURAL COLLEGE.

FIFTH REPORT ON THE PERMANENT EXPERIMENT FIELD.  
1905-1914.

By ARTHUR J. PERKINS, Principal Roseworthy Agricultural College,  
and W. J. SPAFFORD, Assistant Experimentalist.

*(Continued from page 25.)*

## MANURE PLOTS.

1. THE EFFECTIVENESS OF SOLUBLE PHOSPHATIC MANURES ON  
ROSEWORTHY SOILS.

The wonderful effectiveness of water soluble phosphatic manures over the great bulk of the South Australian wheat area does not, perhaps, stand in need of any further demonstration. It has indeed become so thoroughly recognised by all concerned that few farmers ever dream of putting in a wheat or hay crop without an accompanying dressing of superphosphate. Official statistical data show that whereas in 1897 only 2.92 per cent. of the total area under cultivation in South Australia was dressed with phosphates, this percentage had risen to 56.77 per cent. in 1905, and to 85.68 per cent. in 1913. The measure of the effectiveness of these manures on the Roseworthy soils may be gauged by data set out in Table XXII. In this table we have compared the results from wheat grown without manure since 1905, with those from neighboring plots dressed regularly with 2cwts. of 36-38 per cent. superphosphate. These results represent the average of two sets of "No manure" plots (Plots 26 and 27, 52 and 53), and of two corresponding sets of 2cwts. superphosphate plots (Plots 28 and 29, 58 and 59). In every case the wheat crops have been preceded by one year of bare fallow.

| 1908                  | 1          | 16 | 1   | 2 15 84                | +                    | 54.82 |
| 1909                  | 2          | 2  | 4   | 2 12 66                | +                    | 25.11 |
| 1910                  | 1          | 17 | 104 | 2 8 14                 | +                    | 26.88 |
| 1911                  | 1          | 0  | 34  | 1 9 29                 | +                    | 44.11 |
| 1912                  | 0          | 17 | 63  | 1 9 64                 | +                    | 68.38 |
| 1913                  | 0          | 7  | 78  | 0 14 90                | +                    | 92.34 |
| Means                 | 1          | 8  | 86  | 1 19 60                | +                    | 37.43 |

We may note in the first place that land without manure since 1905 has, over a period of nine years, averaged 16bush. per acre per annum; whilst over the same period of time, land immediately adjoining, dressed with 2cwts. of superphosphate, has averaged 21bush. 49lbs. This represents an average increase in favor of the superphosphate of 5bush. 49lbs., or 36.35 per cent. With wheat at 3s. 6d. a bushel, this gives 20s. 4d. by way of surplus gross returns, and with superphosphate at 4s. 6d. a cwt., 11s. 4d. an acre by way of net profits from the use of manure.

If now we turn to the total produce figures, with a view to noting the influence of superphosphate on hay yields, for reasons already given, we shall have to look upon total produce figures as representing only 82 per cent. of actual hay yields. In these circumstances we find land permanently unmanured since 1905 yielding in hay an average of 1 ton 15cwts. 9lbs. to the acre over a period of nine years. Similarly, over the same period, wheat dressed regularly with 2cwts. of 36-38 per cent. superphosphate yielded an average of 2 tons 8cwts. 24lbs. to the acre. This represents an increase to the credit of the manure of 13cwts. 15lbs., or 37.43 per cent. If we assume wheaten hay to have an average local value of 35s. a ton, this increase represents a gain in gross returns of 22s. 11d., and a net profit of 13s. 11d. an acre.

It may be noted that the influence of superphosphate on wheat has been felt fairly uniformly by the plant, both in its capacity as a grain yielder—to the extent of an improvement of 36.35 per cent. above “No manure,” and as a producer of hay—to the extent of 37.43 per cent.

## 2. THE INFLUENCE OF “SEASON” ON THE EFFECTIVENESS OF PHOSPHATIC DRESSINGS.

A glance at the percentage increases attributable to the use of superphosphate indicated in Table XXII. will serve to show that the influence of this manure has varied very considerably with the seasons. In a general way, we think it may be stated that the advantages attributable to superphosphate are far more apparent in years of low rainfall than is the case in wet years, and particularly than in those in which the season is artificially lengthened by cold weather and late rains. These facts will be brought out more clearly in Table XXIII., in which we have averaged the percentage increases according to a division of the seasons indicated in Table V. earlier in this report.

TABLE XXIII.—*Showing Average Percentage Increases of Wheat Treated with 2cwt. of Superphosphate over Unmanured Wheat, 1905-13.*

| AVERAGE PERCENTAGE INCREASE ABOVE UNMANURED WHEAT. |        |        |            |
|----------------------------------------------------|--------|--------|------------|

| 1905                                               | +      | 30.91  | .. + 39.72 |
| Seasons normal—                                    |        |        |            |
| 1910                                               |        |        |            |
| 1906                                               | +      | 20.66  | .. + 23.79 |
| Seasons below average—                             |        |        |            |
| 1912                                               |        |        |            |
| 1911                                               | +      | 52.02  | .. + 43.49 |
| 1907                                               |        |        |            |
| Seasons very much below average—                   |        |        |            |
| 1913                                               | +      | 184.28 | .. + 92.34 |

These figures show very clearly that, both in the matter of grain and in that of hay, the benefits derived from the use of superphosphates are proportionately greater in the poor than in the good seasons. The explanation of these facts appears to us simple enough. If there is one thing under our conditions of climate that is outwardly characteristic of the growth of wheat dressed with superphosphate, it is the early and vigorous start of the crop, which almost invariably enables it to outstrip the unmanured crop, and ripen off its grain earlier than the latter. On the other hand, we are all familiar with the suddenness with which early summer drought and heat are apt to set in in normal seasons, bringing to an abrupt close the active growing period of our cereal crops. Hence it follows that in normal seasons the slower growing unmanured crops behave, as a rule, like varieties of wheat

that are too late for the district in which they are sown, and are unable to ripen off their grain under favorable conditions. And it is in this sense that a crop dressed with superphosphate, because of its more rapid growth, may be said to require less moisture for its full development than an unmanured crop. Let the early summer prove cool, however, let early summer rains prove abnormally abundant, and we shall generally find the slow growing unmanured crops tending to catch up in the matter of grain production those treated with superphosphate, and eventually yielding far more heavily than could possibly have been anticipated from their general appearance earlier in the season. Their recovery in the matter of straw growth is not, as a rule, equally pronounced; and unmanured are, as a rule, vastly inferior to those dressed with superphosphate, whatever the character of the season.

In this connection it may be taken to be a very fortunate coincidence that the advantages of superphosphates on our soils should have been championed most vigorously over the long years of the great drought. In more prosperous seasons the task had been more arduous, since the advantages attaching to the use of the manure would have been less strikingly apparent, and a general revolution in farming practice would have been infinitely more difficult to carry to successful issue. Hence the practice of using superphosphate on our wheat crops, which has already added many millions of bushels to the wheat production of the Commonwealth, we must look upon as one of the unrecognised benefits of a long period of drought.

In support of what has been said above, we submit below in Table XXIV. a comparison between the vegetative periods of wheat dressed with 2cwts. of superphosphate on the one hand and wheat grown without manure on the other.

TABLE XXIV.—*Showing Number of Days Elapsing between Characteristic Periods of Vegetation of Unmanured Wheat and of Wheat Dressed with Superphosphate.*

| 1911 .....  | 126                                                   | 121                  | 46                                                 | 47                   | 172                                                 | 168                  |
| 1912 .....  | 114                                                   | 109                  | 45                                                 | 42                   | 159                                                 | 151                  |
| 1913 .....  | 89                                                    | 80                   | 38                                                 | 44                   | 127                                                 | 124                  |
| Means ..... | 126                                                   | 122                  | 45                                                 | 46                   | 171                                                 | 168                  |

We see, therefore, that the records of nine years show that in the Roseworthy district King's White wheat, dressed with superphosphate, has an active growing period represented by 168 days, and of 171 days when unmanured. Admittedly, the difference between these two figures is not very great; it should be recollected, however, that under our climate the ripening off of all varieties, be they late or be they early, takes place as a rule very suddenly, and within a very limited space of time, and that when that time comes, those varieties yield heaviest which are most forward and nearest the term of natural maturity. Hence, in comparing together early and late varieties, the flowering stage is always a safer guide than the ripening stage. And we may note from Table XXIV. that manured wheat invariably comes into bloom earlier than unmanured wheat, whence we may conclude that in normal years the former is always closer to normal maturity than the latter when summer drought begins to put a close upon further growth.

### 3. THE INFLUENCE ON THE WHEAT CROP OF HEAVY AND LIGHT DRESSINGS OF PHOSPHATIC MANURES.

It is one thing to show that phosphatic manures exercise a favorable influence on the growth of our crops, but quite another to determine in what quantities these manures can be used to best advantage on our soils. The terms "heavy" and "light" as applied to these dressings have no more than a relative value, and must necessarily vary in their significance with the country to which they happen to be applied. Here in South Australia the dressings usually availed of would certainly be looked upon as very light in most countries. The average quantity of superphosphate per acre, for instance, used between 1909 and 1913 was about 83lbs., an altogether inconsiderable dressing.

In the Permanent Experiment Field we have a series of plots which have been regularly dressed with varying quantities of superphosphate since 1905. Full data concerning these plots are shown below in Table XXV.

TABLE XXV.—*Showing the Effects of Varying Quantities of Superphosphate, 1905-1913.*

| Means.....                | 1               | 18 | 63 | 1        | 18 | 77 | 1        | 19 | 85 | 1        | 19 | 69  |
| Percentage increase ..... | —               |    |    | + 0.32 % |    |    | + 2.77 % |    |    | — 0.36 % |    |     |

We notice in the first place that for the nine years under consideration, mean maximum yields, both in grain and hay resulted from the use of 2cwts. of 36-38 per cent. superphosphate to the acre. The increases above mean yields of plots dressed with 1wt. of superphosphate are, however, by no means vary marked, viz., 6.55 per cent. in the matter of grain, and 2.77 per cent. in the matter of hay.

From another point of view, the use of an additional hundredweight of superphosphate having a value of 4s. 3d., had the effect of raising the mean grain yield by 1bush. 19lbs., having a value of 4s. 7d. at 3s. 6d. a bushel. The same additional quantity of manure has had the effect of raising the mean total produce yield by 1wt. 8lbs., or the equivalent of 1wt. 34lbs. of hay, representing a value of 2s. 3d. at 35s. a ton.

We may conclude, therefore, from the above data, that at average ruling rates for grain and hay, the use of the additional hundredweight of superphosphate was profit-bearing in the matter of grain, but resulted in a loss where hay crops are concerned.

We must also note that the additional hundredweight in the 3wt. plots did not have any appreciable effect on yields of either grain or hay; and we must conclude that under the conditions of working, wheat yields cannot be influenced by raising the dressings of superphosphate above 2cwts.

We must point out here that the soil of the Permanent Experiment Field is not virgin soil, and that all these plots have, prior to 1905, been more or less heavily manured ever since 1882, and that in consequence the plots dressed with lighter quantities of manure are still profiting from earlier generous treatment. It is for this reason that similar plots were established in 1909 on recently purchased land, which was known not to have been dressed with superphosphate in the past. The plots are known as the "Grainger" plots full details concerning the yields of which are shown below in Table XXVI.,

|                                       | —                                                                             |    |              | —            |              |    | —            |    |              | —            |    |     |

It will be noted that in Table XXVI., whilst total produce returns are given for four consecutive seasons, grain returns are given only for three. This is the case because in 1911 these plots were so badly affected by red rust that it was not thought worth while to reap them for grain.

It may be noted, further, that both in the matter of grain and of total produce or hay, the  $\frac{1}{2}$ cwt. superphosphate plot shows a very substantial increase over the no-manure plots, viz., in the means of the four seasons 69 per cent. and 35 per cent. respectively; that the value of this increase, 18s. 11d. in the matter of grain at 3s. 6d. a bushel, and 13s. 8d. in the matter of hay at 35s. a ton; and that the net increases are respectively 16s. 8d. and 11s. 5d. with superphosphate at 4s. 6d. a hundredweight.

The increases of the 1cwt. plots over the  $\frac{1}{2}$ cwt. plots, although less pronounced, are still profit-bearing, being 15 per cent. and 22 per cent. respectively for grain and hay; and the net profit for the extra  $\frac{1}{2}$ cwt. of superphosphate being represented by 7s. 3d. per acre for grain and 9s. 5d. per acre for hay.

In the matter of grain, on the other hand, there are no appreciable increases in the yields of the 2cwts. and 3cwts. plots above the 1cwt. plot. In the matter of hay there are light increases, neither of which, however, are profit-bearing.

It should perhaps be added that the seasons under consideration are hardly sufficient in number to warrant any very definite conclusions on the subject.

#### 4. INFLUENCE OF HEAVY AND LIGHT DRESSINGS OF SUPERPHOSPHATE ON THE GRAZING CAPACITY OF LAND TEMPORARILY LEFT OUT OF CULTIVATION.

It frequently happens in the practice of South Australian farming that arable land is temporarily left out of cultivation for one or more years. During this interval the land is generally grazed with livestock, and constitutes, therefore, temporary pasture land. This practice is not without its advantages from the purely cropping point of view ; since in the absence of any suitable crop to alternate with wheat, grazing gives the land the respite and repose it craves for. We need not dwell on this aspect of the question since it has been dealt with in the earlier pages of this report. In the great majority of cases the seeding of these temporary pastures is left to nature, and the grazing available therefore consists for the most part of weed growth and cereal plants escaped from the preceding harvest. In cases, that are far too exceptional however, forage crops, in the shape of oats, pease, rape, &c., are sown over these areas. The results, in so far as the after effect of superphosphate is concerned, remain the same in either case, and we are not called upon to differentiate between them in the present discussion.

It may be said to be a fact of almost universal experience that wherever a liberal use has been made of phosphatic dressings the grazing value of pasture land has been very considerably enhanced. Of this world-wide fact we have had ample experience here in South Australia, although it is true that, as a rule, it is only indirectly that our pasture lands have received any phosphatic manures. This manure, applied directly to wheat, has not been exhausted by the crop, but has made its stimulating influence extend to the grazing years, when the land is out of cultivation. The general experience is that the character of the herbage has been changed since superphosphates have come into general use ; leguminous plants, formerly very rare, now tend to predominate ; and ordinary grass and weed herbage appears to have become more palatable and nourishing.

There is no doubt that this improvement in pastures is noticeable even on those farms on which very light dressings of superphosphate are the rule. It is far more pronounced, however, on those farms, like the College Farm, on which relatively heavy dressings have prevailed. In other reports it has been shown how high has been the sheep-carrying capacity of the College Farm within recent years, and we must attribute this economic advantage

very largely to the practice of dressing ordinary wheat crops with 2cwts. of superphosphate to the acre. The College Farm, too, offers clear proof that even a comparatively heavy dressing like 2cwts. of superphosphate to the acre is not immediately effective in the way of markedly increased livestock carrying capacity. Recently purchased fields, for example, which have received three or four phosphatic dressings, are very far from having the sheep-carrying capacity of the fields of the older farm heavily dressed with phosphates since 1880.

This point concerning the relative influence on pastures of heavy and light dressings of phosphates, we have endeavored to test in the plots of the Permanent Experiment Field. We have grown wheat on the land every third year, one year being given to bare fallow and one to grazing; in the several plots the land has received respectively  $\frac{1}{2}$ cwt., 1cwt., 2cwts., and 3cwts. of 36-38 superphosphate whenever under wheat. Full data concerning grazing on these plots are shown below in Table XXVII.

TABLE XXVII.—*Showing Influence of Heavy and Light Dressings of Superphosphate on Sheep-carrying Capacity of Land.*

Value of grazing at 15s. per sheep per annum—£2 9s. 8d.

It will be noted that in Table XXVII. we have split up the grazing available on land left out of cultivation for one year into three periods, viz., (1) stubble grazing, extending between January and March inclusively; (2) the actual grazing 12 months, when the land is out of cultivation, from April to March inclusively; and (3) the three months, April to June, which usually precede fallowing operations. In the aggregate these three periods represent 18 months grazing. In everyday practice they often offer more extended grazing facilities. Thus the stubbles might be available in December; the land might not be fallowed until August or September, &c. The figures indicated in the table refer to what has been actually the practice on these plots.

It may be noted that throughout, although the differences are, perhaps, not very great, the grazing capacity of the land has risen with the quantity of superphosphate applied to the land. In summary, the 18 months' grazing has a value in sheep per acre per annum of—

|                           |      |       |                               |
|---------------------------|------|-------|-------------------------------|
| $\frac{1}{2}$ cwt. plots, | 2.71 | sheep |                               |
| 1cwt. " "                 | 2.96 | " "   | or increase of 9.23 per cent. |
| 2cwts. " "                | 3.15 | " "   | " 6.42 "                      |
| 3cwts. " "                | 3.31 | " "   | " 5.08 "                      |

There are two reasons which account for these rather slender differences. Firstly, the fact that the land in question was heavily dressed with phosphates prior to 1905; and secondly, the fact that out of eight seasons, four, 1910-1913, were poor grazing seasons. We anticipate, therefore, that in the course of time the mean differences will become more pronounced.

We now submit similar data from the plots known as "Grainger's," on which the land is known not to have been dressed with phosphates in earlier years.

TABLE XXVIII.—*Summarising Grazing Data for Land not Previously Manured and Carrying Wheat Once in Three Years, Dressed with Varying Quantities of Superphosphate.*

Here again, in spite of the fact that the three years concerned were exceedingly bad grazing years, we note that the grazing capacity of land left out of cultivation rises sensibly with the amount of superphosphate applied to the wheat crop. In summary, the position may be stated as follows:—The farmer applying  $\frac{1}{2}$  cwt. of superphosphate to his wheat crop can carry one-third more sheep than the farmer who uses no manure; the farmer applying 1 cwt. of superphosphate, two-thirds more sheep than he who uses no manure; the farmer applying 2 cwts. of superphosphate, twice as many sheep as the farmer who uses none; and the farmer applying 3 cwts. of superphosphate, two and one-third times as many sheep as the farmer who uses none.

It should be added that these results refer to three poor grazing years. We anticipate that the differences will be even more pronounced as in the course of time the phosphates begin to accumulate in the soil.

#### 5. COMBINED CROPPING AND GRAZING RETURNS FROM THE USE OF VARYING DRESSINGS OF SUPERPHOSPHATE.

Finally, it will be of interest to group together the combined cropping and grazing returns from land dressed with varying quantities of superphosphate. These returns are summarised below in Table XXIX.

TABLE XXIX.—*Showing Average Combined Cropping and Grazing Returns from Land Dressed with Varying Quantities of Superphosphate.*

ON OLD FARM HEAVILY MANURED PRIOR TO 1905 (EIGHT YEARS).

We gather from the above that on the land of the old College Farm, if we take into consideration grazing returns as well as cropping returns, there is advantage in dressing wheat crops with 2 cwts. of superphosphate to the acre. A dressing of 3 cwts. on the other hand, whilst leading to higher gross returns, does not leave a margin of profit after allowing for the cost of the additional hundredweight of manure.

On the new land the three seasons concerned were very poor, and do not justify definite conclusions. Taking the data for what they are worth, we may note that the profit margin does not extend beyond the 1cwt. dressing.

#### GENERAL CONCLUSIONS.

(19) Relatively to an unmanured crop, the improvement from the use of a 2cwt. dressing of superphosphate is represented by 36 per cent. for a wheat crop and 37 per cent. for a hay crop.

(20) The relative improvement in a wheat or hay crop is more pronounced in dry seasons than in wet seasons, and particularly than in late seasons.

(21) A crop dressed with superphosphate comes into bloom earlier, and ripens its grain earlier than an unmanured crop.

(22) At Roseworthy a 2cwts. dressing of superphosphate has given the highest average yields both of grain and of hay.

(23) Average yields arising from the use of 3cwts. of superphosphates are no higher than those from 2cwts. dressings.

(24) The use of superphosphate on the wheat crop very materially improves the livestock carrying capacity of the land when left out of cultivation.

(25) Within the range of dressings of  $\frac{1}{2}$ cwt. to 3cwts. of superphosphate applied to the wheat crop it has been found at Roseworthy that the livestock carrying capacity of the land when left out of cultivation rises proportionately with the dressings of manure used.

(26) In the matter of combined cropping and grazing returns, we find that cash values of these returns exceed cost of manure used, and leave, therefore, a net profit balance up to a 2cwts. dressing of superphosphate. A 3cwts. dressing, whilst leading to higher gross returns, does not pay for the extra hundredweight of manure used.

*(To be continued.)*

#### WESTERN AUSTRALIAN HARVEST FORECAST.

The official preliminary forecast of the grain and hay harvest of Western Australia shows that the effects of the drought will be as serious there as in the other States. The anticipated wheat yield this season is 3,272,330bush., average 2.5bush., compared with a return last season of 13,331,350bush., average 12.2bush., or a decrease, notwithstanding that the area sown this year was 199,504 acres more than last year, of 10,059,020bush. It is expected that the area to be cut for hay this season will be 70,180 acres more than was the case in 1913, but that there will be a decrease of 126,717 tons in the yield. Last year the hay crop was 277,286 tons from 245,487 acres; the anticipated crop this season is 150,569 tons from 315,667 acres.

## SOME OBSERVATIONS ON POTATO SCAB IN SOUTH AUSTRALIA.

[By T. G. B. OSBORN, M.Sc., Professor of Botany, Adelaide University.]

The name scab is given to a diseased condition of the skin of potato tubers, which makes itself apparent as rough brown patches, that are due to an undue production of corky tissue. There are a number of agencies that may give the necessary stimulus for its production, and in investigating an outbreak of scab there is often some considerable difficulty in determining to what agent or agents the damage is primarily due.

Before considering the nature and causes of the injury, it will be useful to briefly consider the structure of the plant that is damaged. In addition to the upright green stems or "tops" produced by the potato plant, there are a number of short underground ones that grow horizontally. At a very early age these begin to swell at their ends, owing to the formation of a large amount of soft tissue that forms chiefly in their pith region. This soft tissue gradually increases in amount, and becomes stored with starch. The potato tuber, thus, is a swollen underground stem; consequently it produces leaves and buds like other stems, only the leaves are reduced to scales, and the buds are more or less sunken in the depressions called "eyes." So far as the plant is concerned, the stored food provides nutriment for next year's growth. We may incidentally remark, then, how shortsighted is the policy of those growers who save only the smallest and poorest tubers for "seed," instead of selecting well-shaped tubers of 2in. to 3in. diameter, that are true to type, and breeding from them.

The soft internal tissue of the potato tuber is protected on the outside by a few layers of cork cells that form the "skin." These cork cells are very small, flattened structures, that fit closely together, forming an almost air and water proof covering. In order that the living tuber may breathe the corky covering is provided in places with breathing pores or lenticels; in these places the cork cells are less closely packed together, so that air can pass between them. If tubers are grown in very damp soil the cells of the lenticels become swollen, and appear as whitish, fluffy pimples on the

skin of the tuber. These enlarged lenticels may be mistaken for disease, which they are not, though they may become centres of attack for fungi and other parasites.

If owing to any cause the skin of the tuber becomes damaged, there is a production of more cork at the place of injury, which results in a closing of the wound. The rapidly-growing tuber may cause this wound to gape further, when more cork is formed, so that over the injured place there forms an unusually thick mass of cork, as it were a rough bark; such a place is known as a "scab."

It will be readily understood that a mere mechanical injury to the tender skin of a growing tuber might be caused by the presence of rough particles in the soil, such as ashes, or be due to burning by lime. This is certainly the case in some instances in England, where

FIG. 1. Two Potatoes from Gumeracha, showing *Oospora* Scab. The fungus appears as a greyish evanescent mould, that in this case practically covers the potato.

scab has been experimentally induced by mixing coal cinders with the soil: but the results of experiments by Mr. McAlpine in Victoria do not support the conclusion that wood ashes are a general cause of scab.

Fungi are not uncommonly the cause of scabbed areas developing on potatoes. There is a so-called scab due to the fungus *Rhizoctonia solani*, which manifests itself in the form of small dark-brown specks, that may be thickly scattered over the surface of the tuber. These specks are not readily removed by washing, but stand out more clearly when wet against the pale brown of the skin. These little brown lumps are composed of a knotted mass of fungus spawn (hyphae), that adheres closely to the surface of the

potato, but does not penetrate beneath it. Hence they usually do no actual damage, though they disfigure the appearance of the tuber. At times, especially in wet soils, a rot of the root, base of the stem, and tubers may be caused by *Rhizoctonia*, so that potatoes showing brown speck of their skins should not be used as seed. Another fungus organism that is considered as the chief cause of scab in the United States of America is *Oospora scabies*. The fungus is visible as a fine greyish mould on the surface of the scabby areas (Fig. I.). It is only noticeable when the tubers are freshly dug, for it quickly dries up on exposure to the air, hence the specimens that were submitted to me, or that I collected in the field, were sent to the laboratory for examination embedded in the soil in which they grew. Abundant evidence of the occurrence of *Oospora* has been

FIG. II. "Redskin" Potato, showing "Millipede" Damage. The surface of the tuber is channelled by the gnawing of the animals.

FIG. III. "Redskin" Potato, showing Eel-worm Damage. At the bottom of the picture the "blisters" are as yet unbroken, but above they have caused cork-covered wounds that are further enlarged by Millipedes, Thrips, &c.

found on scabbed tubers in South Australia, but in the cases examined it was not possible to say definitely that the fungus was the original cause of the injury; it probably occurred as a complication, producing considerable damage, it is true, but following upon some primary cause due to another agent. In this respect my conclusions are in general agreement with those of Mr. McAlpine, in Victoria.

Potatoes are very commonly damaged by eel-worms, especially in certain districts. These minute internal parasites live in the soft

tissue of the tuber near the skin, which they cause to rise in blister-like swellings. These "blisters" later become broken, so causing an open wound, over which cork forms. Mr. McAlpine states that "in all the leading districts where potatoes are grown the eel-worm has been found, and I have no hesitation in saying that it is the main cause of the so-called scab." Abundant evidence of the damage due to eel-worms has been found in this State on potatoes from Mount Compass, Mount Gambier, and other potato-growing districts. When the injury is in the "blister" stage it is easily recognisable, but later, when the "blisters" are broken and a corky covering forms over the wound, it is not so easy to recognise eel-worms as the original cause. This is because there are present in the soil many other animal organisms that prey upon the outside of the potato tuber, especially if this be already damaged, such are the larvæ of the "click beetle" (*Lacon* sp.), which are known as "wire worms," millipedes, *thrips*, etc. Of these organisms the millipedes were probably the most important in the cases I have examined. Numbers of a small pale-yellow millipede, about half an inch long, have been found on the diseased tubers. These organisms may extend their operations over the whole of a tuber, cutting trenches, as it were, along the surface (Fig. II.). The wounds so caused are closed by cork formation, but the further depredations of the millipede, aided by the minute *thrips*, cause a wound of considerable size. The attacks of these animals, following upon the primary damage of eel-worms, may complete the disfigurement of a tuber (Fig. III.).

A grower near Gumeracha has had his crop rendered almost unsaleable for some seasons past by the severe scabbing of the tubers. The specimens he submitted showed only slight signs of eel-worm, *Oospora* also was present, but it was not clear that the damage was wholly due to either agency. A small quantity of seed was obtained from him, and, by the kindness of Mr. Quinn, I was able to conduct a few experiments at the Government Orchard, Blackwood, on land that has not long been broken and that has not been under crop before. The experiments were on a small scale, and were directed rather to determine the cause of the damage, though incidentally tests were made of well-recognised methods of treatment. Out of the stone weight of seed available not more than 3lbs. of unblemished tubers could be found. These were divided into three lots, while another three lots were selected from the scabbed seed. Two lots of tubers, one scabbed and the other unscabbed, from the sample were planted without treatment as a control. A second pair of lots

(scabbed and unscabbed) were soaked three hours in formalin solution (1oz. to 2galls. of water), while a third pair of lots were treated for two hours with corrosive sublimate solution\*, 1oz. to 8galls. of water. The plot received a light dressing of superphosphate. The dry summer probably affected the yield unfavorably, though the plot was occasionally irrigated. The results may be tabulated as below:—

## NEW ZEALAND PINK EYE.

| Seed.           | Treatment.          | Yield.       |                                           | Remarks.                                                   |
|-----------------|---------------------|--------------|-------------------------------------------|------------------------------------------------------------|

| Scabbed .....   | —                   | 3lb. 8ozs.   | 8ozs.                                     | Eelworms, millipedes, thrips, little oospore.              |
| Unscabbed ..... | —                   | 1lb. 8ozs.   | 8ozs.                                     | Eelworms, millipedes, thrips.                              |
| Scabbed .....   | Formalin            | 5lbs. 14ozs. | 1lb. 4ozs.                                | Millipedes, thrips.                                        |
| Unscabbed ..... | Formalin            | —            | 3lbs.                                     | Perfectly clean, one seed tuber rotted in ground.          |
| Scabbed .....   | Corrosive sublimate | 1lb. 8ozs.   | 15ozs.                                    | Four seed tubers rotted in ground, millipedes, and thrips. |
| Unscabbed ..... | Corrosive sublimate | —            | 3lbs. 8ozs.                               | Perfectly clean.                                           |

While the experiments were on too small a scale to have any great value, they have, nevertheless, a certain interest. Owing to the

FIG. IV. "Redskins" raised in experiment, using unscabbed seed and pickling in formalin. Note the crop is quite free from blemish.

small numbers of tubers involved, it was possible to examine each tuber separately in the laboratory immediately after lifting, so that

\*This is highly poisonous, and corrodes metals. It must be mixed and used in wooden vessels only.

a careful search could be made for parasitic organisms. It is at least worthy of note that in each lot of tubers where scab occurred, in addition to eel-worm, millipedes and thrips were found; in most cases actually being caught in the channelled scabbing.

A second point worthy of notice is that where a "pickle" had been used upon *unscabbed* seed, no sign of blemish was visible upon the crop (Fig. IV.); but *unscabbed seed without treatment* gave a high percentage of scabbed tubers. This clearly shows that the damaging agency is transmissible by contact with diseased tubers. It seems hardly necessary to point out that scabbed seed that was not treated gave a high yield of diseased tubers.

Thirdly, *scabbed seed even after treatment with a "pickle"* (Fig. V.) gave a scabbed yield, possibly owing to the resistance of the

FIG. V. "Redskins" raised in experiment, using scabbed seed, but pickling with formalin. Note the crop is badly scabbed, showing that the eggs of the parasites can survive pickling in diseased tubers, thus emphasising the need for using clean seed.

eggs of the parasites to the poisons, also that the eggs were probably to some extent protected by the cork of the scab. In the case of eel-worms the egg-walls are known to be very resistant to the penetration of poisons, and, further, the eggs are often buried in the tuber beyond reach of any "pickle," so that on no account should any scabbed or blistered tubers be used for seed.

In spite of the small scale of these experiments the conclusion that in this case the main cause of injury was due to the combined action of eel-worms and millipedes appears justifiable. Nor can the advantage that arises from using *unblemished seed and treating that with*

*some pickle*, such as formalin or corrosive sublimate, which is both insecticide and fungicide, be overlooked. The labor involved is not great, and the cost of the chemicals but a few pence, so that the procedure should be "worth while," even to a grower who is not troubled to any serious extent with scab. If the pickling is carefully carried out, there should be no danger of impairing the germination capacity of the seed.

There yet remains the question of what is to be done with land upon which potatoes are grown that already produces scabby crops. This is often a serious problem in this State, for land that will grow potatoes is limited in extent, and consequently is put under the same crop more often than would be the case if there were other land available. It is suggested that on potato-growing land that has already produced its crop the tops, roots, and weeds should be raked together and burnt after the crop is lifted, as they only provide further food for millipedes and thrips. The eggs of the parasites, however, are in the soil, and it is probable that treatment with "aptesite," "vaporite," or other of the insecticide preparations might be of value. Experiments in this direction would be useful, but the matter being a zoological rather than a botanical one, it will not be pursued from this laboratory.

---

## PHOSPHATIC MANURES.

---

ADDRESS BY THE DIRECTOR OF AGRICULTURE.

---

*(Continued from page 412.)*

---

### RELATIVE VALUE OF HEAVY OR LIGHT DRESSINGS OF PHOSPHATIC MANURES.

It is well known that there are differences of opinion as to the relative values of heavy or light dressings of phosphatic manures. I do not think anyone is in a position to "lay down the law" for a vast area of country like that represented in the South Australian agricultural areas. I admit that it is a question that has to be settled locally, and in this respect, those who have looked into the

matter for themselves are perhaps best able to tell what is best for the district. It has to be recognised that the amount of manure used in one country is no criterion for another country. For example, if in England they were told that it was the custom to use only 83lbs. in South Australia, farmers there would say that this was a useless dressing. In some cases, in that country, as much as half a ton of basic slag is used. Nor is it a question of ascertaining what dressing will give the largest return of wheat or hay, but what dressing will prove the most profitable one to apply.

Table VI., printed below, gives the results for nine years of wheat grown with varying dressings of phosphates. The dressings varied from  $\frac{1}{2}$ cwt. to 3cwts. per acre. It must be admitted that the results are not very striking in their differences.

| Mean Bushel<br>Weight ..... | 62 $\frac{1}{2}$             | 62 $\frac{1}{2}$ | 62 $\frac{1}{2}$ | 62 $\frac{1}{2}$ |                                                               |

Mean difference between 1cwt. and 2cwt. plots = 1bush. 19lbs., at 3s. 6d. a bushel = 4s. 7d.

It may be noted that whilst the average yields do not show any very marked difference, nevertheless maximum yields are shown as the result of the use of 2cwts. of superphosphate to the acre, and this is the dressing I have adopted as the standard dressing for the College Farm. The difference between the 1cwt. plot and the 2cwt. plot for the nine years under consideration is only 1bush. 19lbs., which at 3s. 6d. a bushel represents 4s. 7d., or just about the value of the additional cwt. of manure. On the other hand, the 3cwt. plots yielded no more than the 2cwt. plots, and in this connection we may feel certain that there is nothing to be gained on the Rose-worthy soils by using a dressing in excess of 2cwts. of superphos-

phate. It should be stated in this connection that the fields on which these plots were placed formed part of the old farm, and have, therefore, been more or less heavily manured ever since 1883. No doubt the difference between the several plots would have been more striking if we had been dealing with virgin land, or, at all events, land that had not previously been manured. In Table VII. it will be noted that the hay returns from crops dressed with varying quantities of superphosphates are similar in character to those already indicated for the grain returns.

Whilst on the subject of heavy dressings of superphosphate, it is possibly as well that some reference be made to their alleged tendency to lead to the blighting off of the crop. This appears to be a very common opinion among some farmers. It would appear to have arisen from the known influence of farmyard manure in the same direction. The influence of farmyard manure on the general growth of the crop is very different from the influence of superphosphate. Farmyard manure gives rise to a soft, sappy growth, which renders the crop very liable to blighting off under the influence of early hot winds. Superphosphate, on the other hand, generally gives rise to strong, hardy growth, and after an experience of 10 years in the matter, I am convinced that superphosphate, however heavy the dressing, does not in any way tend to help the blighting off of crops. As a fair proof of this I would point to the average bushel weights indicated in Table VI. It will be noted that these average bushel weights for the nine years are practically the same, whatever the dressing of super. used, and if there is one thing that is characteristic of blighted crops, it is a low bushel weight. I agree, however, that in certain instances, a heavy dressing of super. may possibly have an indirect influence which may lead to blighting off. Heavy dressings of super. applied to the wheat crop, for example, usually result in increasing very considerably the grazing capacity of the land in the year that follows. Now, I have known cases in favorable seasons when land has carried as much as four sheep to the acre for the year. This heavy carrying capacity is the indirect result of the use of heavy dressings of super., and another indirect result of the super. is the heavy dressing of sheep manure which this land will have received as the result of the heavy grazing. When land of this kind comes again under crop, it may result in a rank, sappy growth, which will be more liable to blight off than another crop. I have seen examples of this happen, particularly in light land, but it must be noted that these influences can only indirectly be set down to the use of heavy dressings of superphosphate.

| Means ..... | 2 7 3           | 2 7 20          | 2 8 54          | 2 8 35          | + 2.77                                                        |

Mean difference between 1cwt. and 2cwt. plots = 1cwt. 34lbs. of hay, at 35s. a ton = 2s. 3d.

### INFLUENCE OF PHOSPHATIC MANURES ON THE SHEEP-CARRYING CAPACITY OF LAND.

The influence of phosphatic manures, however, goes beyond the yield of the crops to which it has been applied, and it is worth noting that although comparatively heavy dressings of superphosphate do not appear to give very great immediate profits, their influence extends beyond the cereal crop to the sheep-carrying capacity of the land when left out of cultivation. There is no doubt that phosphatic manures have completely transformed the character of our pastures. They have changed the nature of the herbage, which is now very highly leguminous, and the character of the natural herbage appears to have become strengthened, and the herbage is more nutritious, more fattening, and better calculated to build up a strong healthy body in young livestock. It may be added that at the Roseworthy Agricultural College we noticed that this important change in pastures is far more marked in land that is heavily dressed with superphosphates than in land receiving only light dressings. In a general way, it may be stated that the sheep-carrying capacity of the fields of the old farm is infinitely greater than the sheep-carrying capacity of more recently purchased fields. Apart from that, the evidence of the results tabulated in Table VIII. will show that the sheep-carrying capacity is directly proportional to the amount of superphosphate applied to the wheat crop when the land is under crop.

| Means .....                          | 1.87                         | 2.08                    | 2.16            | 2.31            |
| Value at 15s. per sheep .....        | 28s. 0 $\frac{1}{2}$ d.      | 31s. 2 $\frac{1}{2}$ d. | 32s. 5d.        | 34s. 8d.        |
| Percentage increase .....            | —                            | + 11.23 %               | + 3.85 %        | + 6.94 %        |

The practice adopted in connection with these tests is to weigh the sheep as they are put on to the plots, and also when they are taken off. They are never allowed to lose weight on the plots. As soon as they show signs of coming to a standstill, they are removed.

A perusal of the table does not, perhaps, reveal very striking differences, but there are two good reasons for this: The land had been heavily manured before it was set aside in 1905 for experimental plots, and, secondly, the last four years were bad grass years. This means that the carrying capacity has been materially reduced during these years, and the advantages of super. less apparent.

Table IX., on the other hand, deals with land that had never been dressed with superphosphate before it was used for these tests, and in the case of these plots the differences are very striking. Notwithstanding the fact that the three years in question, as previously pointed out, were not good grass years, the "no-manure" plot carried an average of .39 sheep per acre per year; that which had received  $\frac{1}{2}$ cwt. per acre with the wheat crop carried an average of .52 sheep per acre per year; 1cwt., .66 sheep; 2cwts., .83 sheep; and 3cwt. 1.03 sheep per acre per year. This means that a farmer can carry, under conditions similar to those existing at the College, one-third more sheep on the land which had previously been dressed with  $\frac{1}{2}$ cwt. of super. per acre when left out to grass than he could on land that had not received any manure with the wheat crop; similarly, land that had received a 3cwt. dressing with the crop will carry two and two-thirds more sheep than unmanured land.

In this connection it may be noted that as the manure accumulated in the land, so the carrying capacity improved to the extent that

the College Farm can, with an average season, at present carry one sheep to the acre over its whole arable area—a strong argument in favor of heavier dressings of superphosphate whenever one wishes to combine wheatgrowing with sheep, which, to my mind, is the most profitable practice one can adopt on the average Lower North farm.

TABLE IX.—*Showing Sheep-carrying Capacity of Plots on New Land not previously Manured but Regularly Dressed with Varying Quantities of Superphosphate when under Wheat since 1910.*

## SOLUBILITY OF PHOSPHATIC MANURES.

Experience shows that over the great bulk of South Australia, the only form of phosphatic manures that are of any value are those that are said to be water soluble, i.e., in the form of superphosphate. This, however, is not the case in many other countries, e.g., there are many countries in which bonedust is a very popular form of manure; this is the case, for example, in New Zealand and Tasmania, and even locally it has still many advocates among our market gardeners and those able to make a free use of irrigation waters, so much so, that at the present moment bonedust has acquired an almost fictitious value as a manure when compared with superphosphate. It is true, of course, that bonedust brings with it, in addition to phosphoric acid, a certain amount of nitrogen; not sufficient, however, to justify the price that is sometimes paid for it. Even more insoluble is ordinary ground phosphatic rock, a manure which in some wet countries is said to be effective. Generally

speaking, however, our climatic conditions are such that our soils respond only to water-soluble superphosphate, i.e., a phosphatic manure easily soluble in water and immediately available to the roots of growing plants. In this connection one is sometimes asked to state whether one brand of superphosphate is better than another. There is only one answer to a question of this kind. The value of the superphosphate depends, first, on the guaranteed analysis, and, second, on the extent to which it is dry and free-running. Farmers are therefore able to judge for themselves of the value of any brand submitted to them, independently of what may be said in their favor by the agents. The brands usually sold here are said to be 36-38 per cent. superphosphate, and perhaps a few words of explanation in connection with the meaning of this term may not be out of place:—36-38 per cent. means that this manure contains the equivalent of 36-38 per cent. of tri-calcium phosphate rendered soluble in water. It is perhaps a clumsy way of expressing the position, but has become more or less consecrated by practice, and there is nothing much to be gained in advocating a change of expression. We may note, however, that 36-38 per cent. of tri-calcic phosphate rendered soluble means actually 16.95 per cent. of phosphoric acid, the real active element which is purchased in the manure, and at £4 5s. per ton, we are paying for this phosphoric acid at the rate of 5s. per unit, whilst the tri-calcic phosphate rendered soluble is at the same rate worth 2s. 3½d. per unit; 1cwt. of 36-38 per cent. superphosphate will contain about 19lbs. of phosphoric acid.

Quite recently the claims of a richer form of superphosphate have been put forward, and superphosphate going 45-47 per cent. is at present on the market, and on examining it we have found it both dry and free-running. The price asked for this manure is £5 per ton, which works out at 2s. 2d. per unit of tri-calcic phosphate rendered soluble. It is, therefore, relatively cheaper than the 36-38 per cent. brands, being actually worth at the same unit price £5 5s. 8d. per ton. In favor of the richer phosphate is, of course, the fact that transit expenses would be lighter. It may be stated that 90lbs. of the 45-47 per cent. superphosphate would go as far as 1cwt. of the 36-38 per cent.

#### QUANTITIES OF PHOSPHORIC ACID TAKEN FROM THE SOIL BY CROPS.

Some farmers are apt to look upon a 1cwt. dressing of superphosphate to the acre as being a very liberal allowance towards the requirements of a crop. In this connection an inspection of

Table X. will show that large quantities of phosphoric acid are taken up by various types of crops. We may note in this connection that the 15bush. crop of wheat will take 14.2lbs. of phosphoric acid per acre, that a 20bush. crop of wheat will take 18.9lbs. per acre, that a 40bush. crop will take 37.9lbs. of phosphoric acid per acre. On the other hand, we have seen that the amount of phosphoric acid in 1cwt. of 36-38 per cent. super. is only 19lbs., and corresponds therefore exactly to the requirements of a 20bush. crop of wheat, but no more. We must realise therefore that independently of any other consideration, if we wish to maintain our land in good heart, and make it capable of carrying successive heavy crops, we must at least restore to it quite as much phosphoric acid as the crop removes from the ground; particularly is this the case since phosphoric acid is one of those substances which are not replaced in our soils from time to time from natural sources. We have already noted that the supplies in our soils are very limited in some cases, and if we exhaust them by a few heavy crops, the chances are that the quality of the land will deteriorate fairly rapidly, unless we make good these losses by comparatively heavy dressings of superphosphates.

TABLE X.—*Showing Amount of Phosphoric Acid taken from the Soil by various Crops.*

| Crops.            | Yields.<br>Bushels. | Phosphoric Acid<br>in Lbs. per Acre. |
|-------------------|---------------------|--------------------------------------|
| Wheat .....       | 15                  | 14.2                                 |

# WILL SUPER. WHICH HAS BEEN APPLIED TO THE LAND IN 1914 RETAIN ALL ITS VIRTUES IN 1915, IF THE 1914 CROP WAS A COMPLETE FAILURE?

This is the question which was originally put to me by members of the Branch, and I would say that a reply to it depends very largely on circumstances, some of which we may consider. We can feel tolerably certain in the first place that superphosphate once placed in the land is not wasted, even if the crop, as is generally the

case, does not use it wholly. We have already seen, for example, that superphosphate applied to a wheat crop has the effect of materially improving the grazing capacity of the land in the years that follow. This shows that the effects of the super. are lasting, and not wasted. Another fact to be observed is that you find very little phosphates in drainage waters. This means that water washing through the soil, whilst it dissolves substances like nitrates, lime, common salt, &c., does not leach out the phosphates. We infer, therefore, that the superphosphate placed in the ground in 1914 will still be there in approximately the same place, unless it is ploughed under to a greater depth in 1915; but will it retain its full strength and its full value? That, of course, is quite another question, and it would be as well to consider first what happens to superphosphate when it is brought in contact with moist soil. It is said to "revert," i.e., it loses some degree of its original water solubility. What happens in general is that the fresh super. combines with the carbonates of the soil, chiefly with lime, and becomes neutral, and as such less soluble. It may be noted here that unless the super. reverted in this fashion, it would represent a standing danger to vegetation. The young rootlets of germinating plants are exceedingly delicate, and whenever they come in contact with a strong acid like fresh superphosphate they are exposed to withering away, with the result that the crop would be a failure. This is what happens, for example, when rape seed or kale seed is mixed with fresh super. and sown in dry ground. The seed may germinate under the influence of the slight moisture in the manure, but will perish because the dry soil has not been able to destroy the acid of the super. This, again, is what happens when super. is placed in land insufficiently provided with lime. It does not revert, and for the same reason the roots of the young plants are destroyed. We see, then, that it is essential that this acid super. should revert by contact with the carbonates of the soil. We also know that this reversion leads to the loss of a certain amount of solubility. In this connection let us note that it is customary to refer to phosphatic manures under three headings. They are said to be acid soluble (like bonedust), citrate soluble (like basic slag), or water soluble (like fresh superphosphate). Now the solubility of reverted superphosphate is somewhere between the solubility of fresh superphosphate and the citrate solubility of basic slag, i.e., it is soluble in the soil moisture charged with carbonic acid gas, and the weak organic acids. This solubility is sufficient for the purpose of the young growing plant, and the reverted super. owes its solubility not so much to its chemical composition, as to its physical properties of

being finely subdivided more or less in a very gelatinous condition. So long as the superphosphate continues in this condition it retains its full value to the crop. We know, for example, from experience that superphosphate drilled in the land, say, in February, is effective as a manure for wheat sown in May. This is generally the case, because at that time of the year the soil is comparatively dry, and reversion will not take place until heavier rains fall. It must be noted, however, that the longer the superphosphate remains in contact with the soil, the more it will tend to harden, and its solubility will approach that of basic slag. I am inclined to think, therefore, that after 12 months' contact with the soil, superphosphate is not likely to continue quite as effective from the point of view of the young growing plant as the recently applied super. No doubt it is very much a question of finance, but if the dressing used in 1914 is a relatively light one, say,  $\frac{1}{2}$  cwt. to the acre, I think it should be repeated again in 1915. If, however, a dressing of 1 cwt. or more had been used in 1914, I would say that probably in 1915  $\frac{1}{2}$  cwt. of dressing would meet the requirements of the case.

## THE HORSE.

### OUTLINES OF ANATOMY FOR FIRST AID.

[By F. E. PLACE, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.]

The three kinds of apparatus in the horse that interest us as horse owners are the breathing apparatus, digestive apparatus, and locomotor apparatus. The defects in the working of the last are generally of a less acute character than those of the other two, and admit of calling in veterinary aid. On the contrary, diseases of the breathing or digestive apparatus are generally best treated at the outset, and it is necessary that we should understand at once the symptoms that will lead us to differentiate one from the other. In order to understand these symptoms it is necessary to have a rough idea of where the organs are, and what they do.

#### The Mouth.

The digestive apparatus commences at the lips; and, no doubt, many have noticed the marked difference between the movements of the horse's lips and those of the cow. In the case of the horse the

lips are thick, mobile, and very sensitive, but in the case of the cow they are thick, not mobile, and not very sensitive. Nature has made the difference for this reason—that the horse has to select amongst his food substances of various character, and various sizes, and he does that with these lips, provided with long tactile hairs. The cow takes things for granted. She puts out her tongue like the arm of a reaper, and draws long rough food into her mouth. In the case of the horse, as soon as the food is held by the lips it is passed to the incisor teeth, the growth of which produces marks which enable us to judge the age of the horse. There are on the top and lower jaw of the horse six incisor teeth—12 in all. In the cow there are no incisor teeth in the upper jaw, their place being taken by a pad of hard gristle, but there are eight in the lower jaw. The duty of these teeth in the horse is to act as scissors, shredding the food up for grinding, so that their surface is irregular and sharp. As these teeth wear with age they become straighter. We find that the temporary teeth are milky, and that all permanent teeth are of a yellowish tinge. The length of the top surface of the permanent teeth at five years is from side to side, and from eight years it is from back to front. The greater length from front to back the greater the age of the horse. The food is cut off by the teeth and passed to the tongue, where it is mixed with saliva. Now, underneath the throat of the horse, and just below the ears, are glands, from whence comes the saliva. During 24 hours these glands pass into the mouth some six or seven gallons of saliva; therefore the horse must be supplied with that amount of fluid from outside, or more than twice the weight of the dry food he consumes. After the food has mixed with the saliva it passes to the grinding teeth, and there it is crushed. If you watch a horse chewing you will see that he begins by chewing the food on one side of his mouth, and then passes it over to the other side, and continues chewing for some 5 to 15 minutes. What is happening is that the upper teeth, having sharp chisel edges on the outside, and the lower the same on the inside, and crossing one another, are by that crossing action tearing the food into shreds and at the same time grinding it by their roughness. The outer enamel is very hard, but the next layer is much softer. I have laid stress upon that point because the teeth are often rasped flat, and then have to be roughened up again by nature. This chewing having gone on, the food is thoroughly mixed and moistened, but probably not much digested by the saliva, and the tongue passes it along the bars of the roof of the mouth till it reaches the back of same.

Now the sense of swallowing is started in these bars, therefore if we want the horse to swallow anything we wish to give him in the

way of a drench, it is better to get the inclination to swallow by dealing with the roof of the mouth rather than the tongue. The drench will not be successful if poured straight into the mouth. If, however, we tickle the roof of the mouth and drop a few drops on the tongue we shall get it over quickly. When the sense of swallowing is set up the muscles at the sides of the throat grasp the food and take it down, possibly in spite of the will of the horse. That muscular action causes the muscular veil at the back of the throat to rise, and as this rises it presses a trap door over the windpipe. The nostrils are above the mouth, but if we cut the horse's neck open we shall find the gullet above the windpipe, so that the food has to rise over the windpipe to pass into the gullet. That happens when the horse's head is down while feeding. In that position the muscles of the throat are quite capable of grasping the food, lifting the veil, closing the door, and passing the food into the gullet; but if we raise the head high we tighten all the muscles and prevent the trap door from closing, therefore pouring the medicine into the windpipe instead of into the gullet. Therefore, if we have to drench we should not rise the head any higher than necessary to get a slight fall on the back of the tongue. The gullet passes between the first ribs, over the heart, through the diaphragm. As soon as it is passed through the diaphragm it becomes very much thicker, probably three times the thickness it is when passing through the chest; this thickness ends in the stomach.

### The Stomach.

The stomach of the horse lies just behind the liver, and is a comparatively small organ, in an average-sized draught horse the capacity being about three gallons. Overfeeding is detrimental, for the food, coming down the gullet, falls into the bag-shaped stomach, which does not turn the food round as does a human being's, but allows it to lie layer on layer. As the food falls, it is gradually pushed along by its own weight, the earlier portions becoming fluid by digestion. When we cut the horse's stomach open we find the first half lined with whitish mucous membrane, and the second with pinkish. These are called the white and pink half respectively. Now only the food in direct contact with the stomach is digested, therefore if we have stuffed the stomach full, only that food around the edges will be acted upon, and that in the centre will be fermented. Fermentation means the production of a large quantity of gas, which causes distension of the stomach, and all sorts of troubles. Now, as the gullet enters the stomach, it is guarded by a thick circular band of muscle, which prevents the horse from vomiting his food, but if

the walls of the stomach are very much damaged, then these muscles lose their power, and the food may be brought up the gullet by pressure of the belly walls. At the outlet there is a syphon trap which prevents food returning from the bowels into the stomach, and in about three hours all that has been put into it has been digested. The food then turns into a creamy fluid, and is passed out into the small bowels. As soon as it passes out it meets with bile passing from the liver. The horse has no gall bladder. His big, strong liver is always making bile, and sending it into the small bowels, about 6in. from the stomach, and at the same time juice from the pancreas, which is something like saliva, goes in with the bile. These two juices together act very rapidly on the food in the small bowels. The bile makes the fats of the food into soap, and disinfects the contents of the bowels and stimulates their muscles. The juice from the pancreas has three ferments which act on the three main constituents of food, and extract therefrom the greater part of the nourishment.

The food is then traversing through about 72ft. of small bowels—this passage occupies from about half to three-quarters of an hour. It then passes into one of the big bowels—the caecum or water gut. In the horse this gut commences under the loins, going transversely towards the off side, till it comes to near the end of the breastbone, and is a pear-shaped bag, which has a capacity of about seven gallons, which should be quite fluid and pea-soupy. At that point in a human being there is the appendix. In this point of the water gut you will find an accumulation of sand, grit, &c., which are difficult to pass out. Therefore if the contents of this bowel, instead of being pea-soupy, are hard and dry, the muscle bands round the bowel cannot lift them to the opening above the inlet to pass it into the next big bowel—the four-folded colon. The ordinary pea-soupy contents of this gut will stay there for about 12 hours, during which time numberless germs will be acting on the food. Most of the nourishment of the food has been absorbed by the glands in the small bowels, but the harder parts of the food will be treated in the big bowel. When the food has been thoroughly deprived of its nourishment, it has reached the large four-folded colon on the near side. It now passes down through this big, voluminous gut, often, but wrongly, called paunch, about 4ft. long, to a bend above the breast bone, and is then pushed up through another length to a narrower part within the pelvis bone, then descends to the breastbone again, and then passes up the fourth and last division of the colon. The four divisions hold about 24 gallons of food, and four days have elapsed by the time it has passed right through the horse. The hard, indi-

gested food that remains is passed into the last division of the gut, and there, by muscular action is converted into dung balls, which remain until a convenient time arrives for them to be finally expelled.

### The Kidneys.

When the blood has carried the food from the small bowels to the liver it is treated in different ways there. The blood has been gathering matters that are not wanted and which have to be got rid of—a large quantity in the breath, a large quantity by the sweat, and a large quantity by the kidneys. Of the kidneys, the right is the heavier of the two, and heart-shaped, and the left is a couple of ounces lighter and is kidney-bean shaped. The blood passes through the kidneys, and poisons are extracted from it. The urine passes drop by drop from the kidneys into the bladder by tubes which open between the coats of the sides of the bladder, which expands. It can expand bigger than a football without inconvenience, but if it becomes over distended it pushes the urine back on to the kidneys, but as a rule, before this occurs, the urine is passed out through the neck of the bladder, situated just under the vent on the hinder edge of the pelvis. It relaxes, and the urine flows into the urethra or pizzle pipe, and when it reaches that pipe there are muscles which hurry it along. In the mare the bladder is underneath the vagina—she has no long pizzle pipe as in the male, but there is a flap of mucous membrane on the floor of the vagina which guards its entrance.

### Breathing and Circulatory Organs.

In getting back to the front of the animal we shall consider the breathing and circulatory organs. The horse's nostrils are strengthened with gristle on the inside and outside, and just inside there are two little pouches or bags. These are placed there to assist the nostrils to become very much dilated under pressure of heavy work, to obtain more air. The little pouch is a safety arrangement. The air goes up the nostrils, which are not hollow pipes, but are hollows filled with a paper-like bone covered with a mucous membrane. The lower part warms the air, and the upper part is the organ of smell. Right at the back of the nostril there is a crab-like arrangement of bone in which he recognises pleasurable smells, such as that of the opposite sex. The air passes along through the bones, and reaches the throat. He gets no air through the mouth, but it all goes through the nostrils into the box at the top of the windpipe—the larynx, which is guarded by the epiglottis. The larynx has a small opening fitted with plates of gristle worked by muscles to allow of the

air being regulated as admitted. If the horse was to draw in large quantities of air it would pass down the windpipe and irritate the lungs. The air passes through the windpipe underneath the gullet, and over the heart, where it divides into tubes, one to each lung (bronchi), which are subdivided like the stalks of a bunch of grapes, and breath fills the air cells in the lungs. If you place your ear on the horse's chest a little above the elbow, and pass it along to the last three ribs, you can hear the air entering and leaving the lungs. So, we see, half the trunk contains the lungs, and half the bowels.

The horse at rest breathes about 8 or 10 times per minute air which gives up its oxygen to the red cells of the blood. The blood, which is about one-fifteenth the weight of the animal, is always being circulated by the heart, which is really two hearts in one—the right heart and the left heart, each consisting of a top chamber—the auricle, and a bottom chamber—the ventricle. The top and bottom are separated by valves. For convenience I will imagine that the two lower parts contract together to pump blood, the left pumps it into the chief artery of the body, and the right pumps it into the lungs. Now, after the blood has gone over the various parts of the body it gives out oxygen to the muscles and tissues, and loses its bright red color. It then begins to flow back through veins towards the heart, entering the top of the right heart as blue blood, passing through into the right ventricle, and being forced as blue blood through the lungs, where it receives oxygen. This changes it to a bright red color; it is returned to the top of the left heart, and is then again pumped into the arteries of the body, which are elastic pipes. Now if we pump a fluid into already full elastic tubes obstructed at their distant ends, there will be a wave transmitted along the pipe. This gives us what we call the pulse. When about  $1\frac{1}{2}$  pints of blood are forced into the aorta, an elastic wave is set going, and if we pass the finger down the angle of the jaw we shall feel the pulse wave; this occurs from 35 to 45 times per minute on the average.

The result of this blood circulation is body warmth; the ordinary temperature is about 100deg. When it is ranging from 103 to 105 the animal is suffering from fever. The horse has 18 pairs of ribs, which provide him with a big cage for his lungs, and the bottom of that cage is a narrow breastbone, so that we do not often see the horse resting on his breast, but generally lying on his side, throwing the whole of the weight of the bowels on the belly walls, which are lined with shining membrane—the peritoneum. If there is pain in the bowels, it is very much more painful to stand than to lie down. Therefore a horse with digestive trouble prefers to lie down. The

chest is lined with a similar membrane—the pleura—which supports the lungs, the distension of which is interfered with when the horse lies down, and the two layers of pleura rubbing against each other are painful, so that a horse with chest disease remains standing. The result of good and regular circulation and aeration of the blood with healthy lungs means that the waste matter is thoroughly got rid of by the kidneys, lungs, and skin. Watch a horse swallowing naturally, digesting naturally, passing out dung and water naturally, and then if there are differences in these performances there is something wrong, noticeable in change of attitude or behaviour, and so one is able to locate the disease.

## ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board was held on Wednesday November 9th. Present—Mr. A. M. Dawkins (presiding), Professor Perkins (Director of Agriculture), Messrs. W. J. Colebatch (Principal Roseworthy College), C. J. Tuckwell, C. E. Birks, J. Miller, T. H. Williams (Chief Inspector of Stock), C. J. Valentine, Col. Rowell, C.B., and the Secretary (G. G. Nicholls).

*Preserving Timber.*—A report was received from the Chairman of the Board (Mr. Laffer, M.P.), who had recently visited the Williamstown district in company with Professor Perkins and Mr. A. M. Dawkins, for the purpose of investigating complaints which had been made to Mr. F. Coleman (Vice-chairman) that timber, principally gum, was being destroyed wantonly on the miscellaneous leases in that district. In a report on the trip, Mr. Laffer remarked—"We found that the leases consist of the poorest country, and that all the best land has long since passed into private hands. On comparatively only a small acreage is there any gum timber growing, and the trees are confined to the flats and watercourses. Yet in some places many fine young trees may be seen, and if left to mature should make splendid timber. In other parts the trees are far too thick and must be thinned out to ensure good timber. However, as the leases are so scattered, and the area carrying gums is so small there is little call for special treatment. At the same time every effort should be made to reserve the natural timber on all miscellaneous leases, and to encourage natural afforestation. Although a large number of trees has been felled in past years, there is not much evidence of recent felling. Between Mount Crawford and Lobethal a considerable area of land is held by the Forest Department, and the afforestation of this is proceeding. Complaints have been made that much timber has been burned which might have been sold, but the Conservator of Forests (Mr. W. Gill) states that licences were issued by the department, and as much wood as

possible was sold, but that which has been consumed consisted principally of honeysuckle, for which there was no sale."

*Foxes and Wild Dog Act.*—A communication from the Miltalie Branch of the Bureau suggesting that foxes should be brought under the Wild Dog Act, so that payment might be made for scalps, was received. After discussion, it was decided to refer the matter to the Deputy Surveyor-General (Mr. E. Bitten Jones) for an expression of opinion. It was further reported that the attention of Vermin Boards had been directed to a proposal said to have been made to liberate foxes in certain districts, and the boards had been reminded of the heavy penalty provided under the Act for non-destruction of vermin.

*Conference Districts.*—A proposal that the district comprising the Northern Branches of the Bureau should be divided into two parts, with a view to make the annual conferences more useful and representative, and to secure better attendances, was considered by the Board, and it was decided to adopt the idea. The demarcation of the boundaries was left to the Director of Agriculture and the Secretary.

*Branch Closed.*—It was decided to close the Branch at Dingabledinga on account of lack of evidence of work from that Branch.

*New Branch.*—Denial Bay—G. M. Hare, E. H. Hasting, H. Lindsay, E. J. McDonald, E. A. Hoffrichter, A. Croker, P. McLaren, W. Thiselton, G. Starling, W. H. E. Lutz, A. H. Hoffrichter, J. Crocker, J. F. Bourke, L. J. Hoffrichter, J. Holmes, J. W. Whyborn, J. Waterman, W. Lindsay, B. Whyborn.

*New Members.*—Burra—R. R. Bartholomeus, W. H. Field; Long Flat—C. V. Sabben, J. B. Corcoran; Hartley—D. F. Westwood, J. S. Forbes; Yabmana—M. Robertson; Goode—H. B. Smith; Strathalbyn—J. S. Richardson; Cressy (Mindarie)—E. Threadgold, A. E. Hosking, F. Phillips, A. W. Lower, C. A. Reichstein, E. Docking, E. Reichstein, G. Lower; Mount Compass—W. J. Clarke, H. E. Clarke; Naracoorte—B. J. C. Hansford, S. Hart, R. A. Miles; Port Germein—W. C. Mullighan; Maitland—C. C. Neale, G. Auliffe; Crystal Brook—R. L. Davidson, E. M. Davidson; Glencope—F. Braselmann, E. Braselmann; Morphett Vale—W. Duval, sen.; Myponga—J. Rowley; Kanmantoo—J. Hannam; Carrow—A. E. Norton, B. Gobell; Waikerie—O. Thomas, F. Binks Williams, H. A. W. Jaeschke, Wm. Jones, Wm. Oliver Jones; Yadnarie—A. A. Dreckow; Berri—A. J. Strang; Morchard—H. B. Roberts, F. Loftus, L. G. Toop; Port Germein—P. Colbey, H. Crittenden; Kingston-on-Murray—M. Foster.

### NEW SOUTH WALES HARVEST.

The estimated wheat yield of New South Wales this season is 14,000,000 bushels from 4,000,000 acres.

D. F. LAURIE, Poultry Expert and Lecturer.

## REPORT FOR DECEMBER, 1914.

The weather has been dry and warm. The heat exceeded the century on two or three occasions. The rainfall has been light; the amounts registered were 11 and 37 points on the 13th and 15th respectively—a total fall of 48 points. The general health of the birds has been good; egg-production has been of a satisfactory character, and individual birds in Section III, single testing, have added to what may be considered previous fine scores. Deaths have been recorded as follows:—Five in Section I, six in Section IV., and two in Section III. These occurred chiefly through the excessive heat on the 24th. Broodiness—The single pen sections have accounted for 77 removals as follows:—Forty-seven birds still competing in Section IV., and 24 disqualified birds in same section, while Section III. has provided six. Section I. has returned 32 broodies. Lucerne is still being used in quantity. Seventeen visitors inspected the station during the month; total to date, 1,635.

The market for wheat during December was unsettled; prices in Victoria particularly being very irregular. In New South Wales, legislation was passed giving the Government power to purchase all wheat in the State at a rate to be determined. This was subsequently fixed at 5s. per bushel in the country, which is equivalent to about 5s. 6d. per bushel on trucks, Darling Harbor.

## DAIRY AND FARM PRODUCE MARKETS.

A. W. Sandford & Co., Limited, report on January 1st:—

**BUTTER.**—The temperatures during last month were not as high as the usual December readings, and consequently it was possible to forward and keep dairy produce in better condition than is usually the case during the last month of the year. A heavy turnover has been experienced in all grades of butter, values improving 1d. to 1½d. per lb. all round. "Alfa" sold at 1s. 3½d. per lb.; "Primus," 1s. 2½d.; third grade creamery, 11d. to 11½d.; choice separators and dairies, 11½d. to 1s. 0½d.; well-conditioned stores and collectors', 9d. to 10d.; heated lots down to 8½d.

**EGGS.**—A sharp rise was recorded, buyers operating extensively for Christmas trade, but towards the end of the month values eased. Guaranteed hen, 9d. per dozen; duck, 10d.

**CHEESE.**—The lowering in price stimulated local consumption, and also brought along extra overseas orders, which have kept stocks nicely cleared. Present quotations are from 5½d. to 6½d. per lb. for large to loaf.
